ABSTRACT

Different logic-based knowledge representation formalisms have different limitations either with respect to expressivity or with respect to computational efficiency. First-order logic, which is the basis of Description Logics (DLs), is not suitable for defeasible reasoning due to its monotonic nature. The nonmonotonic formalisms that extend first-order logic, such as circumscription and default logic, are expressive but lack efficient implementations. The nonmonotonic formalisms that are based on the declarative logic programming approach, such as Answer Set Programming (ASP), have efficient implementations but are not expressive enough for representing and reasoning with open domains.

This dissertation uses the first-order stable model semantics, which extends both first-order logic and ASP, to relate circumscription to ASP, and to integrate DLs and ASP, thereby partially overcoming the limitations of the formalisms. By exploiting the relationship between circumscription and ASP, well-known action formalisms, such as the situation calculus, the event calculus, and Temporal Action Logics, are reformulated in ASP. The advantages of these reformulations are shown with respect to the generality of the reasoning tasks that can be handled and with respect to the computational efficiency. The integration of DLs and ASP presented in this dissertation provides a framework for integrating rules and ontologies for the semantic web. This framework enables us to perform nonmonotonic reasoning with DL knowledge bases. Observing the need to integrate action theories and ontologies, the above results are used to reformulate the problem of integrating action theories and ontologies as a problem of integrating rules and ontologies, thus enabling us to use the computational tools developed in the context of the latter for the former.
DEDICATION

To my family
ACKNOWLEDGEMENTS

Several people, directly or indirectly, have played a part in my successful completion of the program. Some people though, deserve a special mention.

First of all, I would like to thank Joohyung for providing me the wonderful opportunity to work with him. I truly appreciate the amount of effort he put into supervising me. I thoroughly enjoyed the numerous discussions we had and can honestly say that I have improved a lot under his supervision. I would also like to thank Chitta Baral, Subbarao Kambhampati, and Vladimir Lifschitz for agreeing to be on my committee. It has been a privilege working with them, and I learnt a lot from each of them.

I am grateful to my current and former teammates, Yunsong, Tae-Won, Michael, Mike, Sunjin, Greg, Joseph, and Jeong-Jin, for the numerous technical (and many more non-technical) discussions. I am also grateful to my friends Shankar, Raju, Luis, and Aravind, and my friends and colleagues at Siemens, Dan, Vinay, Mathaeus, and Anshuman for their help and support.

I am deeply indebted to my parents, my sister, and my brother for their amazing support and understanding. None of this would have been possible without their encouragement. I am also indebted to my cousins and other members of my family for their encouragement. I would like to specially thank my niece, Vanshika, and my nephew, Satvik, for just being so cute and for making me smile.

This work was partially supported by the National Science Foundation under Grants IIS-0839821 and IIS-0916116, the IARPA SCIL program, and Siemens Corporate Research.

Chapter 1

INTRODUCTION

Knowledge representation and reasoning (KR&R) is the area of Artificial Intelligence (AI) that is concerned with encoding knowledge in an adequately expressive formalism and drawing conclusions effectively from the encoded knowledge. A lot of work in the area is based on formal logic, and many logic-based formalisms have been proposed. However, developing a formalism that is both adequately expressive and efficiently computable has remained a constant fundamental challenge.

First-order logic is widely used in KR&R. It forms the basis of many well-known knowledge representation languages. For example, Description Logics (DLs), which are widely studied in the context of the semantic web, are decidable fragments of first-order logic. However, since inference in first-order logic is monotonic, it is not suitable for capturing defeasible inferences (the kind of inferences in everyday reasoning in which we tentatively derive conclusions and retract them in the light of further information). In order to overcome this limitation of first-order logic, there has been extensive research on nonmonotonic reasoning, and many formalisms have been proposed.

Circumscription (McCarthy, 1980, 1986) and Default Logic (Reiter, 1980) are among the first and most well-known nonmonotonic formalisms to have been introduced. These languages extend first-order logic and have been shown to be suitable for representing various commonsense reasoning domains. They were also used to provide elegant solutions to the frame problem, thus achieving one of the important goals of the theory of nonmonotonic reasoning. Some of the well-known action formalisms that use circumscription to solve the frame problem are the situation calculus (McCarthy & Hayes, 1969; Reiter, 2001; Lin, 1995), the
event calculus (Shanahan, 1995; Mueller, 2006), and Temporal Action Logics (TAL) (Doherty, Gustafsson, Karlsson, & Kvarnström, 1998). However, circumscription and default logic are hard to compute and thus lack efficient implementations.

Nonmonotonic reasoning is also studied in the context of logic programs, and a number of declarative languages have been proposed. One of the most well-known declarative logic programming languages is Answer Set Programming (ASP), which is based on the stable model semantics (Gelfond & Lifschitz, 1988). The traditional stable model semantics was shown to be a fragment of default logic but several important extensions of the semantics have been proposed that consider more general programs than the ones considered by the traditional semantics. ASP has a wide range of applications, examples of which include automated product configuration (Tiihonen, Soininen, Niemelä, & Sulonen, 2003), decision support for the space shuttle (Nogueira, Balduccini, Gelfond, Watson, & Barry, 2001) and phylogenetic tree inference (Brooks, Erdem, Erdoğan, Minett, & Ringe, 2007). One of the main reasons for the growing popularity of ASP is the availability of efficient off-the-shelf computational tools known as answer set solvers. ASP also has a rich theory and various mathematical tools are available for the analysis of programs. However, a limitation of ASP is that the semantics considers only Herbrand interpretations (variables are merely place-holders and are eliminated by grounding). This limitation implies that all the objects in the domain being modeled often need to be explicitly specified, which in turn implies that ASP does not effectively handle open domains, as often needed for modeling ontologies. The limitation also makes the analysis of programs difficult as the programs need to be grounded in order to apply the existing mathematical tools.

The above discussion on various well-known formalisms suggests that each formalism has interesting applications but also has certain limitations either
with respect to expressivity or with respect to computational efficiency. The discussion also suggests that the limitations of some formalisms are well-addressed by some other formalisms, which implies that relating or integrating the formalisms is a viable approach to (partially) overcoming their limitations.

Relating cirumscription and ASP enables us to use efficient answer set solvers for computing cirumscriptive action theories, such as theories in the event calculus, the situation calculus, and TAL. This has several advantages. First, given the efficiency of the answer set solvers, ASP-based reasoners are expected to be more efficient on several domains when compared to the existing reasoners for the cirumscriptive theories. Second, since improving answer set computation is a community-wide effort, answer set solvers are constantly improved, and these improvements can be carried over to the computation of the cirumscriptive theories. This implies that the computation of the theories with different underlying formalisms can be improved without specifically focusing on each of the formalisms. Third, since answer set solvers can handle recursive axioms, ASP-based reasoners can handle certain reasoning tasks that cannot be handled by the existing reasoners for the cirumscriptive action theories. Fourth, it enables us to view the underlying formalisms of the cirumscriptive theories as high-level languages for ASP, thus allowing us to combine the corresponding theories with ASP-rules. This is particularly useful if we want to extend the theories by adding expressive ASP-rules such as the transitive closure rules.

Similarly, integrating DLs and ASP enables us to perform nonmonotonic reasoning using DL knowledge bases. Since DLs form the basis for the Web Ontology Language (OWL), integration of DLs and ASP provides a framework for the integration of rules and ontologies, which is a key fragment of the semantic web architecture.
Interestingly, while reasoning about actions and integrating rules and ontologies have largely been treated as separate problems, there are certain applications in which it is useful to relate the two. For instance, consider a medical expert system that is required to assist physicians in diagnosis and treatment of diseases/disorders. Such a system needs to be able to reason with various cause-effect relationships, such as the causes of various diseases/disorders and the effects of various drugs or disorders on the human body. For this, the system needs to have sufficient access to information regarding anatomy, pathology, pharmacology, and other related domains. Since much of this information is available in the form of ontologies, the system also needs to be able to query various biomedical ontologies. So, essentially, the system needs to be able to reason with dynamic domains while using the ontologies as knowledge bases.

While there have been several approaches and computational tools presented for integrating rules and ontologies, there is not much work on integrating (circumscriptive) action theories and ontologies. By using a common semantic framework for relating circumscription to ASP and integrating DLs and ASP, we can reformulate the problem of integrating action theories and ontologies as a problem of integrating ASP-rules and ontologies, thus enabling us to use the computational tools of the latter for the former.

In order to relate circumscription to ASP, and to integrate DLs and ASP, we need to bridge the gap between the underlying logics: first-order logic and the stable model semantics. These languages are syntactically and semantically very different. First, the (traditional) stable model semantics (Gelfond & Lifschitz, 1988) is restricted to rule form while first-order logic considers first-order formulas. Second, the stable model semantics refers to grounding to eliminate variables, which implies that it considers only Herbrand interpretations. On the other hand, first-order logic has no such restriction. Third, the negation under the stable model
semantics is default negation (not) while that in first-order logic is the usual classical negation. In addition to bridging the gap between the logics, we also need to relate circumscription to the stable model semantics.

A recent generalization of the stable model semantics makes our tasks a bit easier since it bridges some of the gaps between first-order logic and the traditional stable model semantics (Gelfond & Lifschitz, 1988). The first-order stable model semantics (FOSM) defined by Ferraris, Lee and Lifschitz (2007, 2011) extends the traditional semantics to first-order formulas. The stable models, according to this new definition, are not restricted to Herbrand interpretations. Further, the stable models are characterized as the models of a second-order sentence, which is similar to that used in the definition of circumscription. Since the first-order stable model semantics incorporates features from first-order logic, circumscription, and the traditional stable model semantics, it provides an ideal framework for relating circumscription to ASP, and for integrating DLs and ASP. Towards accomplishing these tasks and overcoming some of the limitations of the corresponding formalisms, this dissertation

1. investigates the relationship between circumscription and FOSM and presents a uniform approach to reformulate the event calculus, the situation calculus, and TAL in ASP;

2. presents a system for computing descriptions in the event calculus, the situation calculus, and TAL using existing answer set solvers, and demonstrates some of its advantages;

3. presents a FOSM-based approach to integrate DLs and ASP, and relates it to several existing approaches;

4. presents a FOSM-based approach to reformulate the problem of integrating circumscriptive action theories and ontologies as a problem of integrating
ASP-rules and ontologies, and discusses some interesting examples with respect to the healthcare/biomedical domain.

5. investigates several properties of the first-order stable model semantics, which, in addition to being useful for accomplishing the above tasks, also have other interesting applications with respect to overcoming some limitations of ASP.

The document is organized as follows. Chapter 2 gives the necessary background information. Chapters 3-6 present various interesting properties of FOSM and discuss some of their applications. Chapter 5 also presents system F2LP (Formula to Logic Program) that turns formulas in FOSM, under certain conditions, into the syntax of answer set programs. Chapters 7, 8, and 9 present reformulations of the event calculus, the situation calculus, and TAL, respectively, in ASP. These chapters also show how to use F2LP to compute descriptions in these formalisms using existing answer set solvers, and compare this ASP-based computation with some existing reasoning engines for the formalisms. Chapter 10 uses FOSM to integrate ASP-rules and ontologies, and relates this approach to several existing approaches. Chapter 11 presents an interesting combination of reasoning about actions and integrating rules and ontologies, with applications in the healthcare/biomedical domain. Finally, Chapter 12 presents a conclusion.
Chapter 2

BACKGROUND

2.1 The Situation Calculus

The situation calculus is one of the most well-known action formalisms. It was originally introduced by McCarthy (1963). Reiter’s version (Reiter, 2001) of the situation calculus differs from the original version mainly in terms of the interpretation of situations. According to McCarthy, a situation is “the complete state of the universe at an instance of time”. On the other hand, according to Reiter, a situation is the same as its history, which is the finite sequence of actions performed since the initial situation. The frame problem was extensively studied under the situation calculus and many solutions were proposed (see, for example, (McCarthy, 1986; Pednault, 1989; Schubert, 1990; Reiter, 1991)). The literature of the situation calculus is very rich and many languages have been proposed. Here, we consider two well-known languages - Basic Action Theories (BATs) (Reiter, 2001) and Lin’s Causal Theories (Lin, 1995).

BATs were introduced by Reiter and use the approach in (Reiter, 1991) to solve the frame problem. They have implementations based on Prolog, which enables expressive first-order reasoning. These theories are extensively used in Golog (Levesque, Reiter, Lespérance, Lin, & Scherl, 1997) and its extensions ConGolog (Giacomo, Lespérance, & Levesque, 2000) and IndiGolog (Giacomo & Levesque, 1999; Giacomo, Levesque, & Sardiña, 2001; Sardiña, Giacomo, Lespérance, & Levesque, 2004), which are high-level languages for the situation calculus, and which have been shown to be well-suited for various applications such as high-level control of robots (Burgard, Cremers, Fox, Hähnel, Lakemeyer, Schulz, Steiner, & Thrun, 1999), web service composition (McIlraith & Son, 2002), and vision systems (Borzenko, Xu, Obsniuk, Chopra, Jasiobedzki, Jenkin, & Lespérance, 2006). However, a drawback of BATs is that they do not provide an
effective solution to the ramification problem. This drawback is overcome by Lin’s causal theories (Lin, 1995), that use circumscription to solve the frame problem and the ramification problem. However, since circumscription is hard to compute, the computational tools for Lin’s causal theories (Lin, 2003; Lin & Wang, 1999) rely on the reduction of circumscription to first-order logic, which is only possible under certain conditions.

2.2 The Event Calculus

The event calculus was originally introduced by Kowalski and Sergot (1986) in the framework of logic programs but was later extensively developed under the classical logic setting (Shanahan, 1995; Miller & Shanahan, 1999). The work based on classical logic uses circumscription to solve the frame problem and the ramification problem. The event calculus is a very expressive language and can handle a variety of reasoning tasks such as reasoning with compound events and hierarchical planning, reasoning about continuous change, reasoning with indeterminate effects, and reasoning with indirect effects. It has been applied to various areas of science and technology, including open interaction systems (Fornara & Colombetti, 2008), robotics (Patkos & Plexousakis, 2009), software engineering (Classen, Heymans, & Schobbens, 2008), and web service composition (Rouached, Perrin, & Godart, 2006). A key difference between the event calculus and the situation calculus is with respect to the time structures used. While the situation calculus uses a branching time structure, the event calculus uses a linear time structure.

Initial implementations of the event calculus were based on logic programming and mostly handled only abduction and planning problems (see, for example, (Shanahan, 2000)\(^1\)). Later, Shanahan and Witkowski (2004) introduced a SAT-based planner which was shown to be more efficient than the logic

---

\(^1\) http://www.iis.ee.ic.ac.uk/~mpsha/planners.html
programming based planners. However, due to its limited coverage of the event calculus, it solves only 1 out of the 14 benchmark problems (Mueller, 2004) from (Shanahan, 1997, 1999). Mueller (2004) introduced a SAT-based event calculus reasoner that not only solves abduction and planning problems, but also solves other interesting problems such as projection and postdiction. This system is called the DEC reasoner, and is available at

Similar to the computational tools for Lin’s causal theories, the DEC reasoner computes circumscription by reducing it to first-order logic (Lifschitz, 1994). It handles a large fragment of the event calculus (Mueller, 2006) and solves 11 out of the 14 benchmark problems. It has been used for various applications, some of which are listed on its webpage.

2.3 Temporal Action Logics

Temporal Action Logics (TAL) (Doherty et al., 1998) is a class of logics for reasoning about action and change that are based on the *Features and Fluents* framework of Sandewall (1994). Some of the languages that belong to this class are PMON (Sandewall, 1994), PMON-RC (Gustafsson & Doherty, 1996), TAL 1.0 (PMON\textsuperscript{+}) (Doherty, 1996), TAL-C (Karlsson & Gustafsson, 1999), TAL 2.0 (Doherty et al., 1998), and TAL-Q (Kvarnström & Doherty, 2000). By TAL, we refer to the language presented in (Doherty & Kvarnström, 2008) which is essentially the latest kernel of this class of logics. Like the event calculus, TAL also uses a linear time structure. In TAL, *features* represent properties of the world, and *fluents* are functions of time representing the values of the features over time. Unlike the situation calculus and the event calculus, actions in TAL are by default durative, due to which, it provides a suitable framework for representing and reasoning with problems involving *required concurrency* (Cushing, Kambhampati,
Mausam, & Weld, 2007). Among other interesting features of TAL is the support for *durational* fluents. TAL uses circumscription to solve the frame problem, ramification problem, and the qualification problem, and the language is carefully designed so that circumscription in the language can be reduced to first-order logic using “predicate completion” presented in (Lifschitz, 1994).

VITAL\(^2\) is a tool for reasoning about actions using TAL. The tool supports rich features, including ramification constraints, qualification constraints, and durational fluents. It not only generates the models but also provides a visualization of the models, which makes it easier to verify the output. TALplanner\(^3\) (Kvarnström, 2005) is a forward-chaining planner based on TAL. The planner uses domain-dependent control rules specified in the description to prune the search space, which results in a considerable improvement in the efficiency. The planner participated in the second and third international planning competitions (IPC-2000\(^4\) and IPC-2002\(^5\)) and won the “distinguished planner” award in the hand-tailored track of IPC-2000.

2.4 Action Languages

Action Languages are high-level languages that are used to succinctly describe transition systems. Examples include STRIPS (Fikes & Nilsson, 1971), ADL (Pednault, 1989), PDDL (McDermott, Ghallab, Howe, Knoblock, Ram, Veloso, Weld, & Wilkins, 1998), \(\mathcal{A}\) (Gelfond & Lifschitz, 1998), \(\mathcal{B}\) (Gelfond & Lifschitz, 1998), \(\mathcal{C}\) (Giunchiglia & Lifschitz, 1998), and \(\mathcal{C}^+\) (Giunchiglia, Lee, Lifschitz, McCain, & Turner, 2004).

The language STRIPS (Stanford Research Institute Problem Solver), which was introduced in the context of automated planning, is one of the earliest action

\(^2\)http://www.ida.liu.se/~jonkv/vital  
\(^3\)http://www.ida.liu.se/divisions/aiics/aiicssite/projects/talplanner.en.shtml  
\(^4\)http://www.cs.toronto.edu/aips2000/  
\(^5\)http://planning.cis.strath.ac.uk/competition/
languages to be introduced. It forms the basis for several languages that are currently being used to describe planning domains. ADL (Action Description Language) is an extension of STRIPS that allows one to represent conditional effects. PDDL (Planning Domain Definition Language), which can be considered as an extension of ADL, is the official language for the international planning competitions. Over the years, several extensions of PDDL have been proposed. While PDDL (v. 1.2) (McDermott et al., 1998) had roughly the same expressiveness as ADL, PDDL (v. 2.1) (Fox & Long, 2003) introduced durative actions, numeric expressions (for modeling domains involving fluents with numeric values), and plan metrics (such as minimize and maximize for utility-driven planning). PDDL (v. 2.2) (Edelkamp & Hoffmann, 2004) introduced derived predicates, and timed initial literals for modeling exogenous events. PDDL (v. 3.0) (Gerevini & Long, 2005) introduced state trajectory constraints (for specifying constraints over the trajectories) and soft constraints and preferences (for specifying constraints that need not be satisfied but that the user would prefer to see satisfied). PDDL (v. 3.1) is an extension of PDDL (v. 3.0) that allows the range of functions to be non-numeric.

Action language $\mathcal{A}$ (Gelfond & Lifschitz, 1998), which is essentially the propositional fragment of ADL, is based on ASP. In $\mathcal{A}$, effects of actions can be specified using statements such as “$A$ causes $B$ if $C$”, which represents the knowledge that action $A$ has effect $B$ under condition $C$. There are several extensions of language $\mathcal{A}$, including languages $\mathcal{A}_C$ (Baral & Gelfond, 1997) and $\mathcal{B}$ (Gelfond & Lifschitz, 1998) that enable representation of concurrent actions and indirect effects respectively. Action language $\mathcal{C}$ (Giunchiglia & Lifschitz, 1998), which is based on causal logic (McCain & Turner, 1997), provides a convenient way to represent nondeterministic actions and concurrent actions. Further, it allows one to choose which fluent is inertial and which is not. Language
\(\mathcal{C}^+\) (Giunchiglia et al., 2004) extends \(\mathcal{C}\) by providing support for functional fluents and by introducing features such as *action attributes* and *additive fluents*\(^6\) (Lee & Lifschitz, 2001). System CCALC\(^7\) is a SAT-based implementation of an expressive fragment of \(\mathcal{C}^+\), and system COALA\(^8\) is a compiler from action languages to answer set programs which supports several action languages including \(\mathcal{B}\), \(\mathcal{C}\), and a fragment of \(\mathcal{C}^+\).

*Comparison with Circumscriptive Action Formalisms*

While action languages and circumscriptive action formalisms address several common problems in the area of reasoning about actions, there are certain key differences between the two. This section briefly discusses some differences between circumscriptive action formalisms and PDDL, and between circumscriptive action formalisms and the action languages based on ASP and causal logic.

One of the key differences between circumscriptive action formalisms (such as the event calculus, the situation calculus, and Temporal Action Logics) and PDDL is that while the former are based on first-order logic (augmented with circumscription), the latter has a transition system based semantics. Another key difference is with respect to the representation of indirect effects. As we will see in the later chapters, the circumscriptive action formalisms handle direct effects and indirect effects in a similar way. As a result, the value of a fluent can change both as a direct effect of an action and as an indirect effect of a possibly different action. This is in contrast to PDDL (v. 2.2), where “derived predicates” cannot occur in the effect lists of actions. On the other hand, PDDL also has certain interesting features that are not well-studied in the context of circumscriptive action

\(^6\)An additive fluent is a fluent with numerical values such that the effect of concurrently executed actions on the fluent can be computed by adding the effects of the individual actions.

\(^7\)http://www.cs.utexas.edu/~tag/cc/

\(^8\)http://potassco.sourceforge.net/
formalisms. Examples include “plan metrics” and “soft constraints and preferences” discussed above.

Similarly, there are some key differences between circumscripive action formalisms and the action languages based on ASP and causal logic. For example, representation of continuous change and compound events are well-studied in the event calculus but not in the framework of action languages. Another example is the representation of durative actions that is well-studied in TAL and the event calculus but not in the framework of action languages. On the other hand, representation of action attributes and additive fluents are well-studied in C+ but not in the framework of the circumscripive action formalisms.

2.5 Stable Model Semantics and Answer Set Programming

The traditional stable model semantics (Gelfond & Lifschitz, 1988) applies to programs consisting of rules of the form

\[ A \leftarrow A_1, \ldots, A_m, \text{not } A_{m+1}, \ldots, \text{not } A_n \]  

(2.1)

where \( n \geq m \geq 0 \), \textit{not} is default negation, comma(,) represents conjunction and \( A \) and each \( A_i \) are ground atoms. Such programs are traditionally referred to as \textit{normal logic programs} and logic programs under the stable model semantics are often referred to as \textit{answer set programs}. In (2.1), \( A \) is the \textit{head} of the rule and \( A_1, \ldots, A_m, \text{not } A_{m+1}, \ldots, \text{not } A_n \) is the \textit{body} of the rule. Further, \( A_1, \ldots, A_m \) is the \textit{positive} part of the body and \textit{not} \( A_{m+1}, \ldots, \text{not } A_n \) is the \textit{negative} part of the body. If the body is empty, then the rule is called a \textit{fact} and if the head is empty, the rule is called a \textit{constraint}. A program is called \textit{positive} if none of the rules in the program contains the negative part of the body. A set of ground atoms \( X \) is a \textit{stable model (answer set)} of a normal logic program \( \Pi \) if it is the minimal model of \( \Pi^X \), where \( \Pi^X \) is the positive program (\textit{reduct}) obtained by (i) removing all the rules such that for some \textit{not} \( A_i \) in the negative body, \( A_i \in X \), and (ii) removing the
negative bodies of all the remaining rules. According to this semantics, variables in
answer set programs are understood as place-holders, to be replaced by the
ground terms of the underlying signature\(^9\). The semantics was later extended to
programs with classical negation, and disjunction in the head (Gelfond & Lifschitz,

Consider the statements “Normally, birds fly.” and “Penguins do not fly.”
These can be represented by the following program \(\Pi\):

\[
\begin{align*}
\text{flies}(x) & \leftarrow \text{bird}(x), \neg \text{flies}(x) \\
\neg \text{flies}(x) & \leftarrow \text{penguin}(x).
\end{align*}
\]

Here, \(\neg\) represents classical negation. The only answer set of \(\Pi \cup \{\text{bird}(\text{tweety})\}\)
is \(\{\text{bird}(\text{tweety}), \text{flies}(\text{tweety})\}\), representing the conclusion that Tweety flies.
However, the only answer set of \(\Pi \cup \{\text{bird}(\text{tweety}), \text{penguin}(\text{tweety})\}\) is
\(\{\text{bird}(\text{tweety}), \neg \text{flies}(\text{tweety}), \text{penguin}(\text{tweety})\}\), representing the conclusion that
Tweety does not fly. As we can see, the inference here is nonmonotonic.

The stable model semantics was further extended to programs with nested
expressions (head and body can contain arbitrary nesting of default negation,
conjunction and disjunction) (Lifschitz, Tang, & Turner, 1999) and programs with
aggregates and choice rules.

Aggregates are constructs that greatly facilitate encoding. They have been
widely studied in the context of relational databases and nonmonotonic reasoning
(see, for example, (Astrahan, Blasgen, Chamberlin, Eswaran, Gray, Griffiths, King,
Lorie, McJones, Mehl, Putzolu, Traiger, Wade, & Watson, 1976; Mumick,
Pirahesh, & Ramakrishnan, 1990; Zaniolo, Arni, & Ong, 1993; Agarwal, Agrawal,
Deshpande, Gupta, Naughton, Ramakrishnan, & Sarawagi, 1996)). They were first
introduced in ASP in the form of weight constraints by Simons, Niemelä and
Soininen (Simons, 1999; Niemelä, Simons, & Soininen, 1999). More general
aggregates were later considered in (Denecker, Pelov, & Bruynooghe, 2001; Pelov, Denecker, & Bruynooghe, 2004; Faber, Leone, & Pfeifer, 2004; Marek & Truszczynski, 2004), and this was followed by various proposals for defining semantics for programs with aggregates (see, for example, (Ferraris, 2005; Son & Pontelli, 2007; Lee & Meng, 2009)).

The following rule intuitively represents that \( p \) is true if there are at least 8 elements that belong to \( q \):

\[
p \leftarrow \#\text{count}\{x : q(x)\} \geq 8
\]

Here \( \#\text{count}\{x : q(x)\} \geq 8 \) is an aggregate expression involving the \( \text{count} \) aggregate. As another example, consider the following rule involving the \( \text{sum} \) aggregate:

\[
p(x) \leftarrow \#\text{sum}\{y : q(x,y)\} \leq 5
\]

This rule represents that \( x \) belongs to \( p \) if the sum of all \( y \) such that \( q(x,y) \) holds is less than or equal to 5.

While most semantics for programs with aggregates agree on the treatment of monotonic aggregates such as \( \text{count} \), they usually differ with respect to the treatment of nonmonotonic aggregates such as \( \text{sum} \). In fact, the need to understand nonmonotonic aggregates under the stable model semantics is one of the main reasons for the several different proposals for semantics of programs with aggregates.

The \( \text{choice} \) construct is another useful construct in ASP, which is used to represent an arbitrary choice for including atoms in the answer set. For example,
consider the following program:

\[
\{ p(x) \} \leftarrow q(x) \\
\]

\[
r \leftarrow p(x) \\
q(a)
\]

The first rule is a choice rule indicating that for every element in \( q \), arbitrarily choose whether the element belongs to \( p \). Since \( q(a) \) holds, the rule generates 2 choices for \( p(a) \): one in which it is true and one in which it is false. As a result, the program has 2 answer sets: \( \{ q(a), p(a), r \} \) and \( \{ q(a) \} \).

Ferraris (2005) extended the stable model semantics to arbitrary propositional formulas. According to that semantics, answer set programs without variables are a special class of propositional formulas. In that paper, he also proposed semantics for aggregates by turning the aggregates to propositional formulas.

The tools that compute answer sets are referred to as answer set solvers. Some of the well-known answer set solvers are SMODELS\textsuperscript{10}, CMODELS\textsuperscript{11}, CLASP\textsuperscript{12}, CLINGO, DLV\textsuperscript{13}, and ASSAT\textsuperscript{14}. SMODELS, CMODELS, and CLASP use the systems LPARSE and GRINGO to ground the input programs. DLV has a grounder built into it, and CLINGO is GRINGO and CLASP combined in a monolithic way. Any of LPARSE, GRINGO, or DLV can be used as a grounder for ASSAT. ASSAT and CMODELS are SAT-based systems, i.e., they turn the output of the grounders into a set of clauses and invoke satisfiability solvers to compute the answer sets.

CLASP\textsuperscript{D} is an extension of CLASP to disjunctive programs, and we use this in place of CLASP whenever necessary.

2.6 Description Logics and Hybrid Knowledge Bases

Description Logics (DLs), which were originally introduced in order to provide precise semantics for network-based systems such as semantic networks and frame systems (Minsky, 1981), are a family of knowledge representation languages, most of which are decidable fragments of first-order logic. DLs have a wide range of applications but are probably most well-known as the basis for the ontology layer in the semantic web. DLs form the basis for the Web Ontology Language (OWL), which is one of the most widely used semantic web languages. OWL today is being extensively used for representing ontologies spanning many different domains. Due to its standard syntax and semantics (based on DLs), it greatly facilitates knowledge sharing across domains. However, the lack of support for nonmonotonic reasoning is a significant limitation of the language. This limitation is well-recognized by the semantic web community, and several approaches have been proposed for integrating nonmonotonic rules and ontologies (DLs). The knowledge base resulting from combining a DL knowledge base with nonmonotonic rules is usually referred to as a hybrid knowledge base.

A hybrid knowledge base is a pair \((T, P)\) where \(T\) is a FOL knowledge base (typically in a description logic) of signature \(\Sigma_T\) and \(P\) is a logic program of signature \(\Sigma_P\). The existing integration approaches can be classified into three categories: loose integration, tight integration with semantic separation, and tight integration under a unifying logic (Nazarenko, Polo, Eiter, de Bruijn, Schwichtenberg, & Heymans, 2010). In the loose integration approach, \(T\) and \(P\) are viewed as separate, independent components, and are connected through minimal safe interfaces for exchanging data (usually in the form of ground atoms). Examples in this category include nonmonotonic dl-programs (Eiter, Ianni, Lukasiewicz, Schindlauer, & Tompits, 2008), and the combination of description
logics and defeasible logic (Wang, Billington, Blee, & Antoniou, 2004). In the \textit{tight integration with semantic separation} approach, \( T \) and \( P \) are more tightly integrated, but the predicates in \( \Sigma_T \) and \( \Sigma_P \) are kept separate. This approach builds an integrated model \( I \) as the union of a model \( I_T \) of \( T \) and a model \( I_P \) of \( P \) with the same domain. Examples in this category are \( r \)-hybrid KB (Rosati, 2005), \( DL + log \) (Rosati, 2006), \( g \)-hybrid KB (Heymans, de Bruijn, Predoiu, Feier, & Nieuwenborgh, 2008), and \( f \)-hybrid KB (Feier & Heymans, 2009). Finally, in the \textit{tight integration under a unifying logic} approach, \( T \) and \( P \) are treated uniformly by translating them into a uniform logic, and there is no principled separation between \( \Sigma_T \) and \( \Sigma_P \). Examples in this category are Hybrid MKNF KB (Motik & Rosati, 2010), the first-order Autoepistemic Logic based integration (de Bruijn, Eiter, Polleres, & Tompits, 2007a), and the Quantified Equilibrium Logic based integration (de Bruijn, Pearce, Polleres, & Valverde, 2007b). This approach is attractive since it provides a seamless integration of DLs and logic programs, and since the information flow is bi-directional.
Chapter 3

CIRCUMSCRIPTION, FIRST-ORDER STABLE MODEL SEMANTICS, AND THEIR RELATIONSHIP

In this chapter, we present a class of formulas, called canonical formulas, on which circumscription and the stable model semantics coincide. As we will see in the later chapters, canonical formulas are general enough to cover theories in the event calculus, the situation calculus, and TAL. This enables us to turn theories in these action formalisms into the first-order stable model semantics.

The chapter is organized as follows. We first review the definitions of circumscription and the first-order stable model semantics. We then introduce canonical formulas and discuss the related work. Several parts of this chapter are also presented in (Kim, Lee, & Palla, 2009; Lee & Palla, 2010), which contain a stronger definition of canonical formulas.

3.1 Circumscription

We assume the following set of primitive propositional connectives and quantifiers:

\[ \bot \text{ (falsity), } \land, \lor, \rightarrow, \forall, \exists. \]

We understand \( \neg F \) as an abbreviation of \( F \rightarrow \bot \); symbol \( \top \) stands for \( \bot \rightarrow \bot \), and \( F \leftrightarrow G \) stands for \( (F \rightarrow G) \land (G \rightarrow F) \).

Let \( p \) be a list of distinct predicate constants \( p_1, \ldots, p_n \), and let \( u \) be a list of distinct predicate variables \( u_1, \ldots, u_n \). By \( u \leq p \) we denote the conjunction of the formulas \( \forall x (u_i(x) \rightarrow p_i(x)) \) for all \( i = 1, \ldots n \) where \( x \) is a list of distinct object variables whose length is the same as the arity of \( p_i \). Expression \( u < p \) stands for \( (u \leq p) \land \neg (p \leq u) \). For instance, if \( p \) and \( q \) are unary predicate constants then \( (u, v) < (p, q) \) is

\[ \forall x (u(x) \rightarrow p(x)) \land \forall x (v(x) \rightarrow q(x)) \land \neg \left( \forall x (p(x) \rightarrow u(x)) \land \forall x (q(x) \rightarrow v(x)) \right). \]
Circumscription is defined in terms of the CIRC operator with minimized predicates. For any first-order formula $F$, expression $\text{CIRC}[F; p]$ stands for the second-order formula

$$F \land \neg \exists u ((u < p) \land F(u)),$$

where $F(u)$ is the formula obtained from $F$ by substituting $u_i$ for $p_i$. When $F$ is a sentence (i.e., a formula with no free variables), intuitively, the models of $\text{CIRC}[F; p]$ are the models of $F$ that are “minimal” on $p$.

This minimization of certain predicates is what makes the inference under circumscription nonmonotonic. For instance, consider again the sentences “Normally, birds fly.” and “Penguins do not fly.” These can be represented using the following formula:

$$\forall x (\text{bird}(x) \land \neg \text{ab}(x) \rightarrow \text{flies}(x)) \land \forall x (\text{penguin}(x) \rightarrow \text{ab}(x)).$$

(3.1)

It follows that

$$\text{CIRC}[(3.1) \land \text{bird}(\text{tweety}); \text{penguin}, \text{ab}, \text{flies}] \models \text{flies}(\text{tweety}),$$

and

$$\text{CIRC}[(3.1) \land \text{bird}(\text{tweety}) \land \text{penguin}(\text{tweety}); \text{penguin}, \text{ab}, \text{flies}] \models \neg \text{flies}(\text{tweety}).$$

The definition of circumscription is straightforwardly extended to the case when $F$ is a many-sorted first-order formula (Lifschitz, 1994, Section 2.4), which is the language that the event calculus, the situation calculus, and TAL are based on.

**Predicate Completion**

Lifschitz (1994) uses the notion of predicate completion to characterize circumscription by a first-order formula under certain conditions.

If $p$ is a predicate constant and $F(x)$ is a formula whose only free variables are the ones in $x$, then replacing the implication $F(x) \rightarrow p(x)$ with $F(x) \leftrightarrow p(x)$ is known as predicate completion.
**Theorem 1** (Lifschitz, 1994) If \( F(x) \) does not contain \( p \), then

\[
\text{CIRC}[\forall x(F(x) \rightarrow p(x)); p]
\]

is equivalent to

\[
\forall x(F(x) \leftrightarrow p(x)).
\]

The above result was extended to the case when several predicates are minimized in parallel. A formula \( F \) is *positive relative* to a list of predicate constants \( p \) if every occurrence of every predicate constant \( p \in p \) in \( F \) is in the antecedent of an even number of implications. Following is a restricted version of Proposition 7.1.1 from (Lifschitz, 1994).

**Theorem 2** If \( F \) is positive relative to \( p \), then

\[
\text{CIRC}[F; p]
\]

is equivalent to

\[
\bigwedge_{p \in p} \text{CIRC}[F; p].
\]

These results are used by the event calculus reasoner DEC reasoner, and the TAL reasoner VITAL for computing circumscription.

### 3.2 First-Order Stable Model Semantics

This review follows the definition by Ferraris et al. (2011).

We assume the same set of primitive propositional connectives and quantifiers as in the case of circumscription (Chapter 3.1).

The stable models are defined in terms of the SM operator with *intensional* predicates,\(^1\) which is similar to the circumscription operator: For any first-order

---

\(^1\)The intensional predicates \( p \) are the predicates that we “intend to characterize” by \( F \), which are analogous to “output” predicates in Datalog; non-intensional (i.e., extensional) predicates are analogous to input predicates in Datalog. Here we use expression \( \text{SM}[F; p] \) in place of \( \text{SM}_p[F] \) used in the work of Ferraris et al. (2011).
formula $F$ and any finite list $p = (p_1, \ldots, p_n)$ of intensional predicates, $SM[F; p]$ is defined as

$$F \land \neg \exists u ((u < p) \land F^*(u)),$$

where $u$ is defined the same as in $CIRC[F; p]$ and $F^*(u)$ is defined recursively as follows:

- $p_i(t)^* = u_i(t)$ for any list $t$ of terms;
- $F^* = F$ for any atomic formula $F$ (including $\bot$ and equality) that does not contain members of $p$;
- $(F \land G)^* = F^* \land G^*$;
- $(F \lor G)^* = F^* \lor G^*$;
- $(F \rightarrow G)^* = (F^* \rightarrow G^*) \land (F \rightarrow G)$;
- $(\forall x F)^* = \forall x F^*$;
- $(\exists x F)^* = \exists x F^*$.

When $F$ is a sentence, the models of $SM[F; p]$ are called the $p$-stable models of $F$. Intuitively they are the models of $F$ that are “stable” on $p$. We will often simply write $SM[F]$ in place of $SM[F; p]$ when $p$ is the list of all predicate constants occurring in $F$.

According to Lee, Lifschitz, and Palla (2008a), answer sets are defined as a special class of stable models as follows. By $\sigma(F)$ we denote the signature consisting of the object, function and predicate constants occurring in $F$. If $F$ contains at least one object constant, an Herbrand interpretation of $\sigma(F)$ that satisfies $SM[F]$ is called an answer set of $F$. The answer sets of a logic program $\Pi$ are defined as the answer sets of the FOL-representation of $\Pi$ (i.e., the
conjunction of the universal closures of implications corresponding to the rules).

For example, the FOL-representation of the program

\[
\begin{align*}
 p(a) \\
 q(b) \\
 r(x) \leftarrow p(x), \textbf{not } q(x)
\end{align*}
\]

is

\[
\begin{align*}
p(a) \land q(b) \land \forall x(p(x) \land \neg q(x) \rightarrow r(x))
\end{align*}
\]

and \(SM[F]\) is

\[
\begin{align*}
p(a) \land q(b) \land \forall x(p(x) \land \neg q(x) \rightarrow r(x)) \\
\land \neg \exists uvw((u, v, w) < (p, q, r)) \land u(a) \land v(b) \\
\land \forall x((u(x) \land \neg v(x) \land \neg q(x)) \rightarrow w(x)) \land (p(x) \land \neg q(x) \rightarrow r(x)))
\end{align*}
\]

which is equivalent to the first-order sentence

\[
\begin{align*}
\forall x(p(x) \leftrightarrow x = a) \land \forall x(q(x) \leftrightarrow x = b) \land \forall x(r(x) \leftrightarrow (p(x) \land \neg q(x)))
\end{align*}
\]

by completion (presented later in the chapter). The stable models of \(F\) are any first-order models of (3.3). The only answer set of \(F\) is the Herbrand model \(\{p(a), q(b), r(a)\}\).

Ferraris et al. show that this definition of an answer set, when applied to the syntax of logic programs, is equivalent to the traditional definition of an answer set that is based on grounding and fixpoints (Gelfond & Lifschitz, 1988).

Note that the definition of a stable model is more general than the definition of an answer set in the following ways: stable models are not restricted to Herbrand models, the underlying signature can be arbitrary, and the intensional predicates are not fixed to the list of predicate constants occurring in the formula. The last fact is not essential in view of the following proposition. By \(pr(F)\) we denote the list of all predicate constants occurring in \(F\); by \(\text{Choice}(p)\) we denote
the conjunction of “choice formulas” \( \forall x (p(x) \lor \neg p(x)) \) for all predicate constants \( p \) in \( p \) where \( x \) is a list of distinct object variables; by \( \text{False}(p) \) we denote the conjunction of \( \forall x \neg p(x) \) for all predicate constants \( p \) in \( p \). We sometimes identify a list with the corresponding set when there is no confusion.

**Proposition 1**  

**Formula**

\[
SM[F; p] \leftrightarrow SM[F \land Choice(pr(F) \setminus p) \land \text{False}(p \setminus pr(F))] \quad (3.4)
\]

is logically valid.

For example, if \( F \) is \( \forall x (q(x) \rightarrow p(x)) \) and \( r \) is a unary predicate, then \( SM[F; p, r] \) is equivalent to

\[
SM[\forall x (q(x) \rightarrow p(x)) \land \forall x (q(x) \lor \neg q(x)) \land \forall x \neg r(x)].
\]

Notice that the (implicit) intensional predicates on the right-hand side of (3.4) are those in \((pr(F) \cup p)\). The \textit{Choice} formula makes the predicates in \((pr(F) \setminus p)\) to be exempt from the stability checking. On the other hand, the \textit{False} formula makes the predicates in \((p \setminus pr(F))\) to be stabilized (i.e., to have empty extents), though they do not occur in \( F \).

The language presented so far does not consider strong (a.k.a. classical) negation. Strong negation is useful to represent the notion of a property being false. This is different from the notion of a property not known to be true, which can be represented using default negation \((\neg)\). Typical uses of strong negation include explicit representation of the Closed World Assumption (CWA) and the commonsense law of inertia. For example, the following axioms represent the knowledge that the property \( \text{on}(x, y) \), representing that an object \( x \) is on \( y \), is

\[\text{Note that this symbol is used to represent classical negation in the logic program syntax discussed in Chapter 2.5. However, in formulas under the first-order stable model semantics, this symbol represents default negation.}\]
inertial:

\[ \text{on}(x, y, t) \land \neg \sim \text{on}(x, y, t + 1) \rightarrow \text{on}(x, y, t + 1) \]
\[ \sim \text{on}(x, y, t) \land \neg \text{on}(x, y, t + 1) \rightarrow \sim \text{on}(x, y, t + 1). \]

Here, ‘\( \sim \)’ is a symbol for strong negation and \( t \) is a time variable. The expression \( \sim \text{on}(x, y, t) \) represents that \( x \) is not on \( y \) at time \( t \). This is different from \( \neg \text{on}(x, y, t) \), which represents that \( x \) is not known to be on \( y \) at time \( t \).

Ferraris et al. (2011) incorporated strong (a.k.a. classical) negation into the stable model semantics by distinguishing between intensional predicates of two kinds, positive and negative. Each negative intensional predicate has the form \( \sim p \), where \( p \) is a positive intensional predicate. An interpretation of the underlying signature is coherent if the extent of every negative predicate \( \sim p \) in it is disjoint from the extent of the corresponding positive predicate \( p \).

According to Ferraris et al. (2011), a formula \( F \) is strongly equivalent to formula \( G \) if, for any formula \( H \) containing \( F \) as a subformula (and possibly containing object, function and predicate constants that do not occur in \( F, G \)), and for any list \( p \) of distinct predicate constants, \( \text{SM}[H; p] \) is equivalent to \( \text{SM}[H'; p] \), where \( H' \) is obtained from \( H \) by replacing an occurrence of \( F \) by \( G \). In other words, replacing a subformula with a formula that is strongly equivalent to the subformula does not change the stable models of the whole formula. While strongly equivalent theories are classically equivalent, the converse does not necessarily hold. Consequently, classically equivalent transformations do not necessarily preserve stable models. For instance, consider \( p \) and \( \neg \neg p \). If \( p \) is intensional, the former has stable models but the latter does not.

Like the extension of circumscription to many-sorted first-order sentences, the definition of a stable model is straightforwardly extended to many-sorted first-order sentences.
The above extension of the stable model semantics to first-order formulas is essentially the same as the extension presented by Lin and Zhou (2011). These definitions are also equivalent to the definition of Quantified Equilibrium Logic given by Pearce and Valverde (2005), which is defined in terms of the logic of Here-and-There. In the rest of the dissertation, we often use FOSM as an abbreviation of first-order stable model semantics.

Relation to Completion

Similar to circumscription, completion can be used, under certain conditions, to characterize the first-order stable model semantics by a first-order formula.

We say that an occurrence of a predicate constant, or any other subexpression, in a formula $F$ is **positive** if the number of implications containing that occurrence in the antecedent is even, and **negative** otherwise. (Recall that we treat $¬G$ as shorthand for $G \rightarrow \bot$.) We say that the occurrence is **strictly positive** if the number of implications in $F$ containing that occurrence in the antecedent is 0. For instance the occurrence of $q$ in

$$(p \rightarrow q) \rightarrow r \rightarrow p$$

is positive, and the second occurrence of $p$ is strictly positive. Let $F$ be a first-order formula. A **rule of** $F$ is an implication that occurs strictly positively in $F$. We say that $F$ is negative on a list of predicates $p$ if members of $p$ have no strictly positive occurrences in $F$.\(^3\)

The **predicate dependency graph** of $F$ (relative to $p$) is the directed graph that

- has all members of $p$ as its vertices, and
- has an edge from $p$ to $q$ if, for some rule $G \rightarrow H$ of $F$,

\(^3\)Note the difference between a formula being negative and an occurrence being negative.
– $p$ has a strictly positive occurrence in $H$, and
– $q$ has a positive occurrence in $G$ that does not belong to any subformula of $G$ that is negative on $p$.

For instance, the dependency graph of (3.5) relative to $\{p\}$ has no edges since the only rule of the formula is the formula itself and $((p \rightarrow q) \rightarrow r)$ is negative on $\{p\}$.

On the other hand, the dependency graph of the same formula relative to $\{p, r\}$ has an edge from $p$ to $r$. Though $p$ occurs positively in $((p \rightarrow q) \rightarrow r)$, there is no edge from $p$ to $p$ since $p \rightarrow q$ is negative on $\{p, r\}$.

A formula $F$ is in Clark normal form (relative to the list $p$ of intensional predicates) if it is a conjunction of sentences of the form
\[
\forall x(G \rightarrow p(x)),
\]
(3.6)
one for each intensional predicate $p$, where $x$ is a list of distinct object variables, and $G$ has no free variables other than those in $x$. The completion (relative to $p$) of a formula $F$ in Clark normal form is obtained by replacing each conjunctive term (3.6) with
\[
\forall x(p(x) \leftrightarrow G).
\]

The following theorem from (Ferraris et al., 2011) relates SM to completion. We say that $F$ is tight on $p$ if the predicate dependency graph of $F$ relative to $p$ is acyclic.

**Theorem 3** (Ferraris et al., 2011) For any formula $F$ in Clark normal form that is tight on $p$, formula $SM[F; p]$ is equivalent to the completion of $F$ relative to $p$.

3.3 Canonical Formulas

Neither the stable model semantics nor circumscription is stronger than the other. For example,
\[
CIRC[\forall x(p(x) \lor \neg p(x)); p]
\]
(3.7)
is equivalent to $\forall x\neg p(x)$, and

$$\text{SM}[\forall x(p(x) \lor \neg p(x)); \ p]$$  
(3.8)

is equivalent to $\top$, so that (3.7) is stronger than (3.8). On the other hand,

$$\text{CIRC}[\forall x(\neg p(x) \rightarrow q(x)); \ p, q]$$  
(3.9)

is equivalent to $\forall x(\neg p(x) \leftrightarrow q(x))$, and

$$\text{SM}[\forall x(\neg p(x) \rightarrow q(x)); \ p, q]$$  
(3.10)

is equivalent to $\forall x(\neg p(x) \land q(x))$, so that (3.10) is stronger than (3.9).

Here, we show that the two semantics coincide on a class of formulas called canonical formulas, which we define below.

We say that a formula $F$ is canonical relative to a list $p$ of predicate constants if

- no occurrence of a predicate constant from $p$ is in the antecedent of more than one implication in $F$, and

- every occurrence of a predicate constant from $p$ that is in the scope of a strictly positive occurrence of $\exists$ or $\lor$ in $F$ is strictly positive in $F$.

**Example 1** The formula

$$\forall x(\neg p(x) \rightarrow q(x))$$  
(3.11)

that is shown above is not canonical relative to $\{p, q\}$ since it does not satisfy the first clause of the definition ($p$ occurs in the antecedent of two implications as $\neg p(x)$ is shorthand for $p(x) \rightarrow \bot$). On the other hand, the formula is canonical relative to $\{q\}$. The formula

$$\forall x(p(x) \lor \neg p(x))$$  
(3.12)
is not canonical relative to \( \{p\} \) since it does not satisfy the second clause; the formula

\[ p(a) \land (\exists x \, p(x) \rightarrow \exists x \, q(x)) \]  

(3.13)
is canonical relative to \( \{p, q\} \), while

\[ p(a, a) \land \exists x (p(x, a) \rightarrow p(b, x)) \]  

(3.14)
is not canonical relative to \( \{p, q\} \) since it does not satisfy the second clause (the second occurrence of \( p \) is in the scope of a strictly positive occurrence of \( \exists \), but is not strictly positive in formula (3.14)).

The following theorem states that, for any canonical formula, circumscription coincides with the stable model semantics.

**Theorem 4**  For any canonical formula \( F \) relative to \( p \),

\[ CIRC[F; p] \leftrightarrow SM[F; p] \]  

(3.15)
is logically valid.

For instance, for formula (3.13), which is canonical relative to \( \{p, q\} \), formulas \( CIRC[(3.13); p, q] \) and \( SM[(3.13); p, q] \) are equivalent to each other. Also, any sentence \( F \) is clearly canonical relative to \( \emptyset \), so that \( CIRC[F; \emptyset] \) is equivalent to \( SM[F; \emptyset] \), which in turn is equivalent to \( F \). On the other hand, such equivalence may not necessarily hold for non-canonical formulas. For instance, we observed that, for formula (3.12) that is not canonical relative to \( \{p\} \), formulas (3.7) and (3.8) are not equivalent to each other. For formula (3.11) that is not canonical relative to \( \{p, q\} \), formulas (3.9) and (3.10) are not equivalent to each other. We also observe that for formula (3.14) that is not canonical relative to \( \{p, q\} \), \( CIRC[(3.14); p, q] \) is not equivalent to \( SM[(3.14); p, q] \): the Herbrand interpretation \( \{p(a, a), p(b, a)\} \) satisfies \( SM[(3.14); p, q] \), but does not satisfy \( CIRC[(3.14); p, q] \).
Note that non-canonical formulas can often be equivalently rewritten as canonical formulas. Since any classically equivalent transformation preserves the models of circumscription, Theorem 4 can be applied to such non-canonical formulas, by first rewriting them as canonical formulas. For example, formula (3.11) is equivalent to
\[ \forall x (p(x) \lor q(x)), \] (3.16)
which is canonical relative to \( \{p, q\} \), so that \( \text{CIRC}[(3.11); p, q] \) is equivalent to \( \text{SM}[3.16]; p, q \). As another example, formula (3.12) is equivalent to
\[ \forall x (p(x) \rightarrow p(x)), \] (3.17)
which is canonical relative to \( \{p\} \), so that \( \text{CIRC}[(3.12); p] \) is equivalent to \( \text{SM}[3.17]; p \). It is clear that this treatment can be applied to any quantifier-free formula (including any propositional formula) because a quantifier-free formula can be equivalently rewritten as a canonical formula by first rewriting it into a clausal normal form and then turning each clause into the form \( C \rightarrow D \) where \( C \) is a conjunction of atoms and \( D \) is a disjunction of atoms.\(^4\)

3.4 Related Work

The relationship between circumscription and the stable model semantics has been well-studied. Proposition 8 from the work of Lee and Lin (2006) shows an embedding of propositional circumscription in logic programs under the stable model semantics. The theorem on canonical formulas is a generalization of this result to the first-order case. Janhunen and Oikarinen (2004) showed another embedding of propositional circumscription in logic programs, and implemented the system \( \text{CIRC2DLP} \),\(^5\) but their translation appears quite different from the one

\(^4\)It appears unlikely that knowledge has to be encoded in a non-canonical formula such as (3.8) that cannot be easily turned into an equivalent canonical formula. c.f. “Guide to Axiomatizing Domains in First-Order Logic” (http://cs.nyu.edu/faculty/davise/guide.html). It is not a surprise that all circumscriptive action theories considered in this dissertation satisfy the canonicality assumption.

\(^5\)http://www.tcs.hut.fi/Software/circ2dlp/.
by Lee and Lin (2006). Ferraris et al. (2007, 2011) showed a characterization of
the first-order stable model semantics in terms of circumscription, and Lin and
Zhou (2011) presented the same via logic of knowledge and justified
assumptions (Lin & Shoham, 1992).

Recently, Zhang, Zhang, Ying, and Zhou (2011) showed that
circumscription of any first-order formula \( F \) can be translated into the first-order
stable model semantics. Theorem 3 from that paper is represented as follows.\(^6\)

**Theorem 5** *(Zhang et al., 2011, Theorem 3)* Let \( F \) be a formula in negation
normal form and let \( p \) be a finite list of predicate constants. Let \( F^\neg\neg \) be the formula
obtained from \( F \) by replacing every \( p(t) \) by \( \neg\neg p(t) \), and let \( F' \) be the formula
obtained from \( F \) by replacing every \( \neg p(t) \) by \( p(t) \rightarrow \text{Choice}(p) \), where \( p \) is in \( p \) and \( t \) is a list of terms. Then \( \text{CIRC}[F; p] \) is equivalent to \( \text{SM}[F^\neg\neg \land F'; p] \).

For example, consider the formula \( F = \forall x(p(x) \lor \neg p(x)) \). According to the above
theorem, \( \text{CIRC}[F; p] \) is equivalent to

\[
\text{SM}[\forall x(\neg\neg p(x) \lor \neg\neg\neg p(x)) \land \forall x(p(x) \lor (p(x) \rightarrow (p(x) \lor \neg p(x)))); p].
\]

Notice that \( F \) is not canonical relative to \( p \), and so, Theorem 4 is not applicable to
\( F \).

The above theorem provides another insight into the relationship between
the two semantics. While the result is applicable to circumscription of any formula,
it requires non-trivial transformations. Our result is limited to canonical formulas,
but does not require any transformation, and is still general enough to cover useful
circumscriptive theories, such as the situation calculus, the event calculus, and
TAL. In fact, we expect that most practical circumscriptive theories satisfy the
canonicality condition.

\(^6\)This is a bit simpler than the original statement because some redundancy is dropped.
3.5 Proofs

We will first review some results from (Ferraris et al., 2011) which will be used in our proofs.

**Theorem 6** (Ferraris et al., 2011, Theorem 2) For any first-order formula \( F \) and any disjoint lists \( p, q \) of distinct predicate constants,

\[
SM[F; p] \leftrightarrow SM[F \land \text{Choice}(q); p, q]
\]

is logically valid.

**Theorem 7** (Ferraris et al., 2011, Theorem 3) For any first-order formulas \( F \) and \( G \), and any list of distinct predicate constants \( p \), \( SM[F \land \neg G; p] \) is equivalent to \( SM[F; p] \land \neg G \).

**Theorem 8** (Ferraris et al., 2011, Theorem 4) Let \( F \) be any first-order formula, \( p \) be any list of distinct predicate constants, and \( p \) be a member of \( p \). If every occurrence of \( p \) in \( F \) belongs to the antecedent of an implication, then the formula

\[
SM[F; p] \rightarrow \text{False}(p)
\]

is logically valid.

**Proof of Proposition 1**

From Theorem 8, it follows that \( SM[F; p] \) is equivalent to

\[
SM[F; p] \land \text{False}(p \setminus \text{pr}(F)).
\]

From Theorem 7, it follows that the above formula is equivalent to

\[
SM[F \land \text{False}(p \setminus \text{pr}(F)); p].
\]

The result follows from Theorem 6. \( \square \)
Proof of Theorem 4

In the following, \( F \) is a formula, \( p \) is a list of distinct predicate constants \( p_1, \ldots, p_n \), and \( u \) is a list of distinct predicate variables \( u_1, \ldots, u_n \) of the same length as \( p \).

Lemma 1 (Ferraris et al., 2011, Lemma 5) Formula

\[
F^*(u) \rightarrow (F^*(u) \rightarrow F)
\]

is logically valid.

Lemma 2 If every occurrence of every predicate constant from \( p \) is strictly positive in \( F \),

\[
(u \leq p) \rightarrow (F^*(u) \leftrightarrow F(u))
\]

is logically valid.

Proof. By induction. We will show only the case when \( F = G \rightarrow H \). The other cases are straightforward. Consider

\[
F^*(u) = (G^*(u) \rightarrow H^*(u)) \land (G \rightarrow H).
\]

Since every occurrence of predicate constants from \( p \) in \( F \) is strictly positive, \( G \) contains no predicate constants from \( p \), so that \( G^*(u) \) is equivalent to \( G(u) \), which is the same as \( G \). Also by I.H., \( H^*(u) \leftrightarrow H(u) \) is logically valid. Therefore it is sufficient to prove that under the assumption \( u \leq p \),

\[
(G \rightarrow H(u)) \land (G \rightarrow H) \leftrightarrow (G \rightarrow H(u))
\]

is logically valid. From left to right is clear. Assume \( u \leq p \), \( G \rightarrow H(u) \), and \( G \).

We get \( H(u) \), which is equivalent to \( H^*(u) \) by I.H. By Lemma 1, we conclude \( H \). □

The proof of Theorem 4 is immediate from the following lemma, which can be proved by induction.
Lemma 3  If $F$ is canonical relative to $p$, then formula

$$(u \leq p) \land F \rightarrow (F^*(u) \leftrightarrow F(u))$$

is logically valid.

Proof.

- $F$ is an atomic formula. Trivial.
- $F = G \land H$. Follows from I.H.
- $F = G \lor H$. Assume $(u \leq p) \land (G \lor H)$. Since $G \lor H$ is canonical relative to $p$, every occurrence of every predicate constant from $p$ is strictly positive in $G$ or in $H$, so that, by Lemma 2, $G^*(u)$ is equivalent to $G(u)$, and $H^*(u)$ is equivalent to $H(u)$.
- $F = G \rightarrow H$. Assume $(u \leq p) \land (G \rightarrow H)$. It is sufficient to show

$$(G^*(u) \rightarrow H^*(u)) \leftrightarrow (G(u) \rightarrow H(u)). \quad (3.18)$$

Since $G \rightarrow H$ is canonical relative to $p$, every occurrence of every predicate constant from $p$ in $G$ is strictly positive in $G$, so that, by Lemma 2, $G^*(u)$ is equivalent to $G(u)$.

- Case 1: $\neg G$. By Lemma 1, $\neg G^*(u)$. The claim follows since $\neg G^*(u)$ is equivalent to $\neg G(u)$.
- Case 2: $H$. By I.H. $H^*(u)$ is equivalent to $H(u)$. The claim follows since $G^*(u)$ is equivalent to $G(u)$.

- $F = \forall x G$. Follows from I.H.
- $F = \exists x G$. Since every occurrence of every predicate constant from $p$ in $G$ is strictly positive in $G$, the claim follows from Lemma 2.

□
Chapter 4

SPLITTING

Splitting in ASP was introduced by Lifschitz and Turner (1994). That paper showed several applications of splitting answer set programs. Among them are the simplification of the computation of answer sets and a simple characterization of locally stratified programs (Przymusinski, 1988). For example, consider the following program:

\begin{align*}
p & \leftarrow \text{not } q, t \\
q & \leftarrow \text{not } t \\
t & \leftarrow \text{not } q
\end{align*}

(4.1)

According to (Lifschitz & Turner, 1994), the above program can be split into two parts, one part consists of the first rule, and the other part consists of the remaining rules. By splitting the program in this way, the answer sets of the program can be computed by first computing the answer sets of the (program consisting of the) last two rules and then using them in the first rule to determine if \( p \) holds or not. This kind of splitting is called top-bottom splitting, wherein we first evaluate the bottom part of the program and then use its answer sets in evaluating the top part. The answer sets of the last two rules are \( \{t\} \) and \( \{q\} \). From the first answer set, we get that \( p \) should hold and from the second answer set, we get that \( p \) should not hold. Thus we get 2 answer sets for the entire program: \( \{t, p\} \) and \( \{q\} \). Erdoğan and Lifschitz (2004) extended the splitting theorem to programs with nested expressions and showed how it can be used to prove correctness of the same. Oikarinen and Janhunen (2008) generalized the splitting theorem in (Lifschitz & Turner, 1994) by considering certain atoms as input atoms.\footnote{The notion of input atoms is similar to the notion of extensional predicates.} For example, consider the program consisting only of rules (4.1) and (4.2). According
to the splitting theorems in (Lifschitz & Turner, 1994) and (Erdoğan & Lifschitz, 2004), the program cannot be split. However, according to the result in (Oikarinen & Janhunen, 2008), the answer sets of the program are the common answer sets of (4.1) (with $t$ as input) and (4.2) (with $q$ as input). Janhunen, Oikarinen, Tompits, and Woltran (2007) apply similar techniques to split disjunctive programs.

The work on splitting discussed above presents some interesting results with respect to simplifying answer set computation and proving correctness of answer set programs. However, the splitting theorems discussed above cannot be applied to programs with variables and programs with aggregates. Since variables and aggregates are integral parts of the ASP language, generalizing the splitting theorem to handle programs with these constructs will enable us to extend the results discussed above to more general classes of programs.

In this chapter, we present a generalization of the splitting theorem in the framework of the first-order stable model semantics. This generalization enables us to extend the splitting theorem to programs with variables, choice constructs, and count aggregates (Chapter 2.5). This theorem is also used in the later chapters to reformulate the event calculus, the situation calculus, and TAL in ASP, and to integrate DLs and ASP.

The chapter is organized as follows. We first present the splitting lemma followed by the splitting theorem. The splitting lemma, which is about splitting the intensional predicates, is used to prove the splitting theorem, which is about splitting a formula into its conjunctive terms. We then introduce RASPL-1 (Lee et al., 2008a), which is a function-free programming language that allows representation of the count aggregate and the choice construct, and show how the splitting theorem can be applied to programs in this language. Several parts of this chapter are also presented in (Lee et al., 2008a; Ferraris, Lee, Lifschitz, & Palla, 2009).
4.1 Generalization of the Splitting Theorem

For the generalization, we use the notion of predicate dependency graph presented in Chapter 3.2. We will denote the predicate dependency graph of $F$ relative to $p$ by $DG_{p}[F]$.

**Splitting Lemma**

Here, we present 3 equivalent formulations of the splitting lemma.

**Theorem 9** [Splitting Lemma, Version 1] Let $F$ be a first-order sentence, and let $p$, $q$ be disjoint lists of distinct predicate constants. If each strongly connected component of $DG_{p,q}[F]$ is a subset of $p$ or a subset of $q$, then

$$SM[F; p, q] \text{ is equivalent to } SM[F; p] \land SM[F; q].$$

Note that the condition on $DG_{p,q}[F]$ in the statement of the theorem holds trivially if all strongly connected components of this graph are singletons.

**Example 2** $F$ is $\neg p \land r \rightarrow q$, $p$ is $p$, $q$ is $q$. In this case, the graph $DG_{p,q}[F]$ has two vertices $p$, $q$, and no edges, so that its strongly connected components are singletons. The splitting lemma asserts that

$$SM[\neg p \land r \rightarrow q; p, q]$$

is equivalent to the conjunction of

$$SM[\neg p \land r \rightarrow q; p]$$

and

$$SM[\neg p \land r \rightarrow q; q].$$

Each of these three expressions can be rewritten as a propositional formula using

**Theorem 3.** Formula (4.3) becomes

$$(p \leftrightarrow \bot) \land (q \leftrightarrow \neg p \land r),$$

(4.6)
(4.4) becomes

\[(\neg p \land r \rightarrow q) \land \neg p, \quad (4.7)\]

and (4.5) turns into

\[q \leftrightarrow \neg p \land r. \quad (4.8)\]

It is clear that (4.6) is indeed equivalent to the conjunction of (4.7) and (4.8).

**Example 3**  \(F\) is \(r \rightarrow p \lor q\), \(p\) is \(p\), \(q\) is \(q\). The graph \(DG_{p,q}[F]\) is the same as in Example 2, and the splitting lemma asserts that

\[SM[r \rightarrow p \lor q; p, q] \quad (4.9)\]

is equivalent to the conjunction of

\[SM[r \rightarrow p \lor q; p] \quad (4.10)\]

and

\[SM[r \rightarrow p \lor q; q]. \quad (4.11)\]

Theorem 3 is not directly applicable to (4.9), but it can be applied to (4.10) and (4.11) by moving the non-intensional predicates to the antecedent. The former is thus equivalent to \(p \leftrightarrow \neg q \land r\) and the latter to \(q \leftrightarrow \neg p \land r\). Consequently (4.9) is equivalent to the conjunction of these two formulas.

Example 3 shows that the splitting lemma allows us to expand the power of completion, as a method for describing stable models, to some disjunctive programs. This is similar to the generalization of completion to disjunctive programs described in (Lee & Lifschitz, 2003); the advantage of the splitting lemma is that it is applicable to programs with variables. For instance, using the same argument as in Example 3, we can check that

\[SM[\forall xy(r(x, y) \rightarrow p(x) \lor q(y)); p, q]\]
is equivalent to the conjunction of

\[ \forall x (p(x) \leftrightarrow \exists y (\neg q(y) \land r(x, y))) \]

and

\[ \forall y (q(y) \leftrightarrow \exists x (\neg p(x) \land r(x, y))). \]

To illustrate the role of the condition on the predicate dependency graph in the statement of the splitting lemma, take \( F \) to be \( p \leftrightarrow q \), with \( p \) as \( p \) and \( q \) as \( q \). The graph \( DG_{p,q}[F] \) in this case has two edges, from \( p \) to \( q \) and from \( q \) to \( p \). The strongly connected component \( \{p, q\} \) of this graph has a common element with \( p \) and a common element with \( q \), so that the splitting lemma is not applicable. Accordingly, the formulas \( SM[p \leftrightarrow q; p, q] \) and \( SM[p \leftrightarrow q; p] \land SM[p \leftrightarrow q; q] \) are not equivalent to each other. Indeed, the former can be rewritten as \( \neg p \land \neg q \), and each conjunctive term of the latter is equivalent to \( p \leftrightarrow q \).

The splitting lemma as stated above can be equivalently reformulated as follows:

**Theorem 10** [Splitting Lemma, Version 2] Let \( F \) be a first-order sentence, and let \( p \) be a list of distinct predicate constants. If \( c^1, \ldots, c^n \) are all the strongly connected components of \( DG_{p}[F] \), then

\[ SM[F; p] \text{ is equivalent to } SM[F; c^1] \land \cdots \land SM[F; c^n]. \]

A loop of a first-order formula \( F \) (relative to a list \( p \) of intensional predicates) is a nonempty subset \( I \) of \( p \) such that the subgraph of \( DG_{p}[F] \) induced by \( I \) is strongly connected. It is clear that the strongly connected components of \( DG_{p}[F] \) can be characterized as the maximal loops of \( F \). For example, the loops of

\[ (p \rightarrow q) \land (q \rightarrow p) \]
relative to \( \{p, q\} \) are \( \{p\} \), \( \{q\} \), and \( \{p, q\} \), while the only strongly connected component is the maximal loop \( \{p, q\} \).

**Theorem 11 [Splitting Lemma, Version 3]** Let \( F \) be a first-order sentence, and let \( p \) be a list of distinct predicate constants. If \( \hat{f}, \ldots, \hat{f}^n \) are all the loops of \( F \) relative to \( p \) then

\[
SM[F; p] \text{ is equivalent to } SM[F; \hat{f}^1] \land \cdots \land SM[F; \hat{f}^n].
\]

The last two versions of the splitting lemma are equivalent to each other in view of the fact that the operator \( SM \) is monotone with respect to the intensional predicates \( p \): if \( p \) contains \( q \) then \( SM[F; p] \) entails \( SM[F; q] \).

**Splitting Theorem**

We now present the splitting theorem, which can be easily proved using the splitting lemma.

**Theorem 12 [Splitting Theorem]** Let \( F, G \) be first-order sentences, and let \( p, q \) be disjoint lists of distinct predicate constants. If

(a) each strongly connected component of \( DG_{p,q}[F \land G] \) is either a subset of \( p \) or a subset of \( q \),

(b) \( F \) is negative on \( q \), and

(c) \( G \) is negative on \( p \)

then

\[
SM[F \land G; p, q] \leftrightarrow SM[F; p] \land SM[G; q]
\]

is logically valid.
Example 4. $F$ is $(\neg q \rightarrow p)$, $G$ is $(\neg p \rightarrow q)$, $p$ is $p$, and $q$ is $q$. $DG_{p,q}[F \land G]$ has two vertices $p$ and $q$, and no edges. So condition (a) in the splitting theorem is trivially satisfied. Further, $F$ is negative on $q$, and $G$ is negative on $p$. The splitting theorem asserts that

$$SM[(\neg q \rightarrow p) \land (\neg p \rightarrow q); p, q]$$

(4.12)

is equivalent to

$$SM[(\neg q \rightarrow p); p] \land SM[(\neg p \rightarrow q); q].$$

(4.13)

One can easily verify this by applying completion (Theorem 3) to each of the formulas under $SM$. As discussed earlier in this chapter, similar result can be obtained by using the splitting theorem by Oikarinen and Janhunen (2008).

4.2 RASPL-1

The language RASPL-1 is based on the observation that the choice construct and the count aggregate can be intuitively represented as first-order formulas, which enables us to straightforwardly use the first-order stable model semantics to provide semantics for programs with these constructs. This implies that we can use the splitting theorem discussed above to split RASPL-1 programs, thus overcoming some of the limitations of the earlier splitting approaches.

RASPL-1 is a function-free programming language that allows representation of the count aggregate and the choice construct.

In RASPL-1, an aggregate expression is an expression of the form

$$b \{x : F_1, \ldots, F_k\}$$

(4.14)

($k \geq 1$), where $b$ is a positive integer ("the bound"), $x$ is a list of variables (possibly empty), and each $F_i$ is an atom possibly preceded by not. This expression is similar to the count aggregate expression presented in Chapter 2.5 and reads:
there are at least \( b \) values of \( x \) such that \( F_1, \ldots, F_k \) hold. Since comma represents conjunction, we can view \( F_1, \ldots, F_k \) as a conjunction of literals.

A rule in RASPL-1 is an expression of the form

\[
A_1 ; \ldots ; A_l \leftarrow E_1, \ldots, E_m, \text{not } E_{m+1}, \ldots, \text{not } E_n \tag{4.15}
\]

\((l \geq 0; n \geq m \geq 0)\), where each \( A_i \) is an atom, each \( E_i \) is an aggregate expression, and semi-colon(;) represents disjunction. A program is a finite set of rules. If an aggregate expression \( E_i \) in (4.15) has the form \( 1\{ : A \} \), where \( A \) is an atom (so that the list of variables in front of the semi-colon is empty) then we will write it as \( A \). If an aggregate expression \( E_i \) in (4.15) with \( i > m \) has the form \( 1\{ : \text{not} \ A \} \) then we will write it as \( \text{not } A \). If \( E_i \) in (4.15) with \( i > m \) is

\[
b \{ x : F(x) \}
\]

then the term \( \text{not } E_i \) can be written as

\[
\{ x : F(x) \} b - 1
\]

Finally, an expression of the form

\[
\{ A \} \leftarrow E_1, \ldots, E_m, \text{not } E_{m+1}, \ldots, \text{not } E_n
\]

where \( A \) is an atom, stands for

\[
A \leftarrow E_1, \ldots, E_m, \text{not } E_{m+1}, \ldots, \text{not } E_n, \text{not not } A.
\]

The semantics of RASPL-1 is defined by a procedure that turns every aggregate, every rule, and every program into a formula of first-order logic, called its FOL-representation.

The FOL-representation of an aggregate expression \( b \{ x : F(x) \} \) is the formula

\[
\exists x^1 \cdots x^b \left[ \bigwedge_{1 \leq i \leq b} F(x^i) \land \bigwedge_{1 \leq i < j \leq b} \neg (x^i = x^j) \right] \tag{4.16}
\]
where \( x^1, \ldots, x^b \) are lists of new variables of the same length as \( x \), and \( x = y \), where \( x = (x_1, \ldots, x_n) \) and \( y = (y_1, \ldots, y_n) \), stands for \( x_1 = y_1 \land \cdots \land x_n = y_n \).

For example, the FOL-representation of \( 2\{x : p(x), \neg q(x)\} \) is

\[
\exists xy((p(x) \land \neg q(x)) \land (p(y) \land \neg q(y)) \land x \neq y).
\]

The FOL-representation of a RASPL-1 rule \( \text{Head} \leftarrow \text{Body} \) is the universal closure of the implication \( \text{Body} \rightarrow \text{Head} \) with each aggregate expression in \( \text{Body} \) replaced by its FOL-representation. The FOL-representation of a RASPL-1 program is the conjunction of the FOL-representations of its rules.

For example, the FOL-representation of the rule

\[
p(x); q(y) \leftarrow 2\{x : r(x)\}, s(x, y)
\]

is

\[
\forall xy(s(x, y) \land \exists xy(r(x) \land r(y) \land x \neq y) \rightarrow p(x) \lor q(y)).
\]

For any RASPL-1 program \( \Pi \) containing at least one object constant, an answer set of \( \Pi \) is an answer set of the FOL-representation of \( \Pi \).

RASPL-1 provides a succinct representation for many known NP-complete problems. For example, the following RASPL-1 program computes cliques of size greater than or equal to \( n \) in a graph \( G=(V, E) \):

\[
\begin{align*}
\text{vertex}(a) & \quad (a \in V), \\
\text{edge}(a_i, b_j) & \quad ((a_i, b_j) \in E), \\
\{\text{in}(x)\} & \leftarrow \text{vertex}(x) \\
\leftarrow \text{in}(x), \text{in}(y), \neg \text{edge}(x, y), \neg x = y \\
\leftarrow \{x : \text{in}(x)\} n - 1
\end{align*}
\tag{4.17}
\]

The first two rules simply declare all the vertices and edges, and the third rule arbitrarily chooses if a vertex belongs to \( \text{in} \) or not. Thus the answer sets of the first
three rules of (4.17) are in a 1–1 correspondence with arbitrary sets $W$ of vertices of the graph. The first of the two constraints in (4.17) eliminates the sets $W$ that are not cliques, and the second constraint eliminates the sets that contain fewer than $n$ vertices.

4.3 Splitting RASPL-1 Programs

Since the semantics of RASPL-1 programs is defined in terms of the first-order stable model semantics, the splitting theorem can be easily extended to these programs. Here, we show how the splitting theorem helps us in proving the correctness of the program (4.17) shown above, which computes cliques of size greater than or equal to $n$ in a graph $G=(V, E)$.

Let the program consisting of the last three rules of (4.17) be $\Pi$. It follows from the splitting theorem that

$$\text{SM}[\Pi^{FOL}; \text{in}] \iff \text{SM}[\text{first}^{FOL}; \text{in}] \land \text{rest}^{FOL}$$

where $\Pi^{FOL}$ is the FOL-representation of $\Pi$, $\text{first}^{FOL}$ is the FOL-representation of the first rule of $\Pi$ and $\text{rest}^{FOL}$ is the FOL-representation of the remaining rules of $\Pi$. Applying completion (Theorem 3) to the theory on the right hand side, it follows that the right hand side is equivalent to

$$\forall x (\text{in}(x) \leftrightarrow (\text{vertex}(x) \land \text{in}(x)))$$
$$\land \forall xy (\neg \text{in}(x) \land \text{in}(y))$$
$$\land \neg \text{edge}(x, y) \land x \neq y$$
$$\land \exists n x (\text{in}(x)),$$

which is in turn equivalent to

$$\forall x (\text{in}(x) \rightarrow \text{vertex}(x))$$
$$\land \forall xy (\text{in}(x) \land \text{in}(y) \land x \neq y \rightarrow \text{edge}(x, y))$$
$$\land \exists n x (\text{in}(x)).$$
If we consider any interpretation $I$ that interprets $vertex$ and $edge$ according to the vertices and edges in the graph, then $I$ satisfies the above formula if and only if $in^I$ represents a clique of size greater than or equal to $n$.

### 4.4 Relevance to Later Chapters

Earlier, we briefly mentioned that the splitting theorem is used to reformulate the event calculus, the situation calculus, and TAL in ASP, and to integrate DLs and ASP. We will now discuss a bit more about this by considering the event calculus. As we will see later in Chapter 7.1, an event calculus description is of the form

$$CIRC[\Sigma ; \text{Initiates, Terminates, Releases}] \land CIRC[\Delta ; \text{Happens}] \land CIRC[\Theta ; Ab_1, \ldots, Ab_n] \land \Xi.$$ 

Using the result on canonical formulas (Chapter 3.3) and the splitting theorem, we can turn the above formula into

$$SM[\Sigma \land \Delta \land \Theta \land \Xi ; \text{Initiates, Terminates, Releases, Happens, } Ab_1, \ldots, Ab_n].$$

In Chapter 7.3, a further transformation is shown that turns the above formula into an answer set program. Similar approach is used to reformulate the situation calculus and TAL in ASP.

### 4.5 Proofs

In this section, we present the proofs of the splitting lemma and the splitting theorem.

**Proof of the Splitting Lemma (Theorem 11)**

We will prove the splitting lemma for a slightly different definition of a predicate dependency graph, and then show how the result can be extended to the definition presented in Chapter 3.2 (which is the one used in the above sections of this chapter).

We say that an occurrence of a predicate constant in a formula is negated if it belongs to a subformula of the form $\neg F$, and nonnegated otherwise. Recall that
a rule of a formula is any strictly positive occurrence of an implication in the formula. For any first-order formula $F$, the predicate dependency graph of $F$ (relative to the list $p$ of intensional predicates), represented by $DG_p[F]$, is the directed graph that

- has all intensional predicates as its vertices, and
- has an edge from $p$ to $q$ if, for some rule $G \rightarrow H$ of $F$,
  - $p$ has a strictly positive occurrence in $H$, and
  - $q$ has a positive nonnegated occurrence in $G$.

Lemma 4 below can be easily proved by induction (Ferraris et al., 2011).

Recall that, about a formula $F$ we say that it is negative on a list $p$ of predicate constants if members of $p$ have no strictly positive occurrences in $F$.

**Lemma 4**: If $F$ is negative on $p$ then

$$(u \leq p) \rightarrow (F^*(u) \leftrightarrow F)$$

is logically valid.

The following lemma extends Lemma 3 from (Ferraris, Lee, & Lifschitz, 2006) to first-order formulas.

**Lemma 5**: Let $p_1, p_2$ be disjoint lists of distinct predicate constants, and let $u_1, u_2$ be disjoint lists of distinct predicate variables of the same length as $p_1, p_2$ respectively.

(a) If every positive occurrence of every predicate constant from $p_2$ in $F$ is negated then

$$((u_1, u_2) \leq (p_1, p_2)) \land F^*(u_1, p_2) \rightarrow F^*(u_1, u_2)$$
is logically valid.

(b) If every nonpositive occurrence of every predicate constant from $p_2$ in $F$ is negated then

\[
( (u_1, u_2) \leq (p_1, p_2) ) \land F^*(u_1, u_2) \rightarrow F^*(u_1, p_2)
\]

is logically valid.

**Proof.** Both parts are proved simultaneously by induction on $F$. Consider the case when $F$ is $G \rightarrow H$; the other cases are straightforward. Then $F^*(u_1, u_2)$ is

\[
( G^*(u_1, u_2) \rightarrow H^*(u_1, u_2) ) \land (G \rightarrow H).
\]  

(a) Every nonpositive occurrence of every predicate constant from $p_2$ in $G$ is negated, and so is every positive occurrence of every predicate constant from $p_2$ in $H$. By the induction hypothesis, it follows that the formulas

\[
( (u_1, u_2) \leq (p_1, p_2) ) \land G^*(u_1, u_2) \rightarrow G^*(u_1, p_2)
\]  

(4.19)

and

\[
( u_1, u_2 ) \leq (p_1, p_2) \land H^*(u_1, p_2) \rightarrow H^*(u_1, u_2)
\]  

(4.20)

are logically valid. Assume $(u_1, u_2) \leq (p_1, p_2)$,

\[
( G^*(u_1, p_2) ) \rightarrow H^*(u_1, u_2) ) \land (G \rightarrow H)
\]  

(4.21)

and $G^*(u_1, u_2)$. By (4.19), we conclude $G^*(u_1, p_2)$. Then, by (4.21), we conclude $H^*(u_1, p_2)$. Then, by (4.20), we conclude $H^*(u_1, u_2)$. (b) Similar. 

The following assertion is a generalization of Lemma 5 from (Ferraris et al., 2006).

**Lemma 6** Let $p_1$, $p_2$ be disjoint lists of distinct predicate constants such that

$DG_{p_1, p_2}[F]$ has no edges from predicate constants in $p_1$ to predicate constants in $p_2$. 

\( p_2 \), and let \( u_1, u_2 \) be disjoint lists of distinct predicate variables of the same length as \( p_1, p_2 \) respectively. Formula

\[
((u_1, u_2) \leq (p_1, p_2)) \land F^*(u_1, u_2) \rightarrow F^*(u_1, p_2)
\]

is logically valid.

**Proof.** By induction on \( F \). Consider the case when \( F \) is \( G \rightarrow H \), so that \( F^*(u_1, u_2) \) is (4.18); the other cases are straightforward. Assume

\[(u_1, u_2) \leq (p_1, p_2) \text{ and } F^*(u_1, u_2) . \]

Our goal is to prove

\[
G^*(u_1, p_2) \rightarrow H^*(u_1, p_2) .
\]

Assume \( G^*(u_1, p_2) \). By Lemma 1, the formula

\[
((u_1, p_2) \leq (p_1, p_2)) \land G^*(u_1, p_2) \rightarrow G
\]

(4.22)

is logically valid. Consequently, from the assumptions above we can conclude \( G \), and, by (4.18), \( H \). Case 1: \( H \) is negative on \( p_1 \). It follows from Lemma 4 that the formula

\[
((u_1, p_2) \leq (p_1, p_2)) \rightarrow (H^*(u_1, p_2) \leftrightarrow H)
\]

is logically valid, and we can conclude that \( H^*(u_1, p_2) \). Case 2: \( H \) is not negative on \( p_1 \), that is to say, \( H \) contains a strictly positive occurrence of a predicate constant from \( p_1 \). Then every positive occurrence of every predicate constant from \( p_2 \) in \( G \) is negated, because otherwise there would exist an edge from \( p_1 \) to \( p_2 \) in \( DG_{p_1, p_2}[F] \). By Lemma 5(a), the formula

\[
((u_1, u_2) \leq (p_1, p_2)) \land G^*(u_1, p_2) \rightarrow G^*(u_1, u_2)
\]

is logically valid. Consequently from the assumptions above we can conclude that \( G^*(u_1, u_2) \). By (4.18), it follows that \( H^*(u_1, u_2) \). Since every edge in \( DG_{p_1, p_2}[H] \) belongs to \( DG_{p_1, p_2}[F] \), by the induction hypothesis applied to \( H \), the formula
\[(\langle \mathbf{u}_1, \mathbf{u}_2 \rangle \leq \langle \mathbf{p}_1, \mathbf{p}_2 \rangle) \land H^*(\mathbf{u}_1, \mathbf{u}_2) \rightarrow H^*(\mathbf{u}_1, \mathbf{p}_2)\]

is logically valid. We can thus conclude that \(H^*(\mathbf{u}_1, \mathbf{p}_2)\). \(\square\)

**Lemma 7** For any formula \(F\) and any nonempty set \(Y\) of intensional predicates, there exists a subset \(Z\) of \(Y\) such that

(a) \(Z\) is a loop of \(F\), and

(b) the predicate dependency graph of \(F\) has no edges from predicate constants in \(Z\) to predicate constants in \(Y \setminus Z\).

The proof is essentially the same as the proof of Lemma 4 in (Ferraris et al., 2006).

**Proof of Version 3 of the Splitting Lemma (Theorem 11).** It is sufficient to prove the logical validity of the formula

\[
\exists \mathbf{u}((\mathbf{u} < \mathbf{p}) \land F^*(\mathbf{u}))
\]

\[
\leftrightarrow \exists \mathbf{u}^1((\mathbf{u}^1 < \mathbf{l}^1) \land F^*(\mathbf{u}^1))
\]

\[
\vee \cdots \vee \exists \mathbf{u}^n((\mathbf{u}^n < \mathbf{l}^n) \land F^*(\mathbf{u}^n)),
\]

where each \(\mathbf{u}^i\) is the part of \(\mathbf{u}\) that corresponds to the part \(\mathbf{l}^i\) of \(\mathbf{p}\), and \(\mathbf{\tilde{u}}^i\) is the list of symbols obtained from \(\mathbf{p}\) by replacing every intensional predicate \(p\) that belongs to \(\mathbf{l}^i\) with the corresponding predicate variable \(u\). **Right to left:** Clear. **Left to right:** Assume \(\exists \mathbf{u}((\mathbf{u} < \mathbf{p}) \land F^*(\mathbf{u}))\) and take \(\mathbf{u}\) such that \((\mathbf{u} < \mathbf{p}) \land F^*(\mathbf{u})\). Consider several cases, each corresponding to a nonempty subset \(Y\) of \(\mathbf{p}\). The assumption characterizing each case is that \(u < p\) for each member \(p\) of \(\mathbf{p}\) that belongs to \(Y\), and that \(u = p\) for each \(p\) that does not belong to \(Y\). By Lemma 7, there is a loop \(\mathbf{l}^i\) of \(F\) that is contained in \(Y\) such that the dependency graph has no edges from predicate constants in \(\mathbf{l}^i\) to predicate constants in \(Y \setminus \mathbf{l}^i\). Since \(\mathbf{l}^i\) is contained in \(Y\),
from the fact that $u < p$ for each $p$ in $Y$ we can conclude that

$$u^i < l^i. \quad (4.23)$$

Let $u'$ be the list of symbols obtained from $p$ by replacing every member $p$ that belongs to $Y$ with the corresponding variable $u$. Under the assumption characterizing each case, $u = u'$, so that $F^*(u) \leftrightarrow F^*(u')$. Consequently, we can derive $F^*(u')$. It follows from Lemma 6 that the formula

$$\left( u' \leq p \right) \land F^*(u') \rightarrow F^*(\tilde{u}^i)$$

is logically valid, so that we further conclude that $F^*(\tilde{u}^i)$. In view of (4.23), it follows that $\exists u^i((u^i < l^i) \land F^*(\tilde{u}^i)).$ \hfill \Box

The splitting lemma can be extended to the predicate dependency graph presented in Chapter 3.2 using the following theorem:

**Theorem 13 (Theorem on Double Negations)** Let $H$ be a sentence, $F$ a subformula of $H$, and $H^-$ the sentence obtained from $H$ by inserting $\neg\neg$ in front of $F$. If $F$ is contained in a subformula $G$ of $H$ that is negative on $p$ then $SM[H^-; p]$ is equivalent to $SM[H; p]$.

**Proof.** Let $G^-$ be the formula obtained from $G$ by inserting $\neg\neg$ in front of $F$. By Lemma 4, the formulas

$$u \leq p \rightarrow (G^*(u) \leftrightarrow G)$$

and

$$u \leq p \rightarrow ((G^-)^*(u) \leftrightarrow G^-)$$

are logically valid. Consequently

$$u \leq p \rightarrow (G^*(u) \leftrightarrow (G^-)^*(u))$$

50
is logically valid also, and so is

\[ u \leq p \rightarrow (H^*(u) \leftrightarrow (H^-)^*(u)). \]

It follows that \( SM[H^-; p] \) is equivalent to \( SM[H; p] \). \( \square \)

Now, let \( F \) be any formula, and \( p \) be any list of intensional predicates. Let \( F^- \) be the formula obtained from \( F \) by replacing every maximal subformula \( G \) of \( F \) that is negative on the intensional predicates \( p \) by \( \neg \neg G \). It is clear that the predicate dependency graph of \( F \) according to the definition in Chapter 3.2 coincides with the predicate dependency graph of \( F^- \) according to the definition above. So, it follows that

\[ SM[F^-; p] \text{ is equivalent to } SM[F^-; l^1] \land \cdots \land SM[F^-; l^n]. \]

The splitting lemma for the dependency graph presented in Chapter 3.2 follows from Theorem 13 above.

*Proof of the Splitting Theorem (Theorem 12)*

By the splitting lemma, \( SM[F \land G; p, q] \) is equivalent to

\[ SM[F \land G; p] \land SM[F \land G; q]. \]

Since \( G \) is negative on \( p \), from Lemma 4, it follows that the first conjunctive term can be rewritten as

\[ SM[F; p] \land G. \quad (4.24) \]

Similarly, the second conjunctive term can be rewritten as

\[ SM[G; q] \land F. \quad (4.25) \]

It remains to observe that the second conjunctive term of each of the formulas (4.24), (4.25) is entailed by the first conjunctive term of the other. \( \square \)
Chapter 5

REDUCING THEORIES IN THE FIRST-ORDER STABLE MODEL SEMANTICS TO ANSWER SET PROGRAMS

While the first-order stable model semantics is an expressive language, it is undecidable in general. An important question to consider is whether there are certain interesting fragments of the language that can be efficiently computed. In this chapter, we show how answer sets of first-order formulas can be computed using existing answer set solvers. In particular, we present translation F2LP (Formula to Logic Program) that turns formulas in the first-order stable model semantics, under certain conditions, into the syntax of answer set programs. This translation is also used in the later chapters to reformulate the event calculus, the situation calculus, and TAL in ASP.

The chapter is organized as follows. We first present an approach to eliminate quantifiers in certain formulas under the first-order stable model semantics. We then introduce translation F2LP, that uses the quantifier elimination approach along with the approach in (Cabalar, Pearce, & Valverde, 2005) that turns quantifier-free formulas into logic programs, to turn formulas under the first-order stable model semantics into the syntax of ASP. We then present system F2LP that implements this translation and produces programs that can be processed by the grounders LPARSE and GRINGO, which are front-ends to various answer set solvers such as SMODELS, CLASP(D), CMODELS, etc. Finally, we discuss the related work. Several parts of this chapter are also presented in (Lee & Palla, 2007; Kim et al., 2009; Lee & Palla, 2010).

5.1 Quantifier Elimination

We introduce a quantifier elimination method that distinguishes between two kinds of occurrences of quantifiers: singular and non-singular. Any non-singular
occurrence of a quantifier is easy to eliminate, while a singular occurrence is
eliminated under a certain assumption.

We say that an occurrence of $QxG$ in $F$ is singular if

- $Q$ is $\exists$, and the occurrence of $QxG$ is positive in $F$, or
- $Q$ is $\forall$, and the occurrence of $QxG$ is negative in $F$.

For example, the occurrence of $\exists x q(x)$ in

$$\exists x \ p(x) \rightarrow \exists x \ q(x)$$

is singular, but the occurrence of $\exists x \ p(x)$ is not.

Non-singular occurrences of quantifiers can be eliminated in view of the
fact that every first-order sentence can be rewritten in prenex form. The prenex
form conversion rules given in Section 6.3.1 of Pearce and Valverde (2005)
preserve strong equivalence.\footnote{Pearce and Valverde (2005) show that a sentence in $\mathbf{QN}_5^c$, the monotonic basis of Quantified
Equilibrium Logic, can be turned into prenex form, from which the result follows.}

\textbf{Theorem 14} \hspace{1em} \textit{Every first-order formula is strongly equivalent to a formula in prenex
form.}

For example, the formula (5.1) is strongly equivalent to

$$\forall x \ \exists y \ (p(x) \rightarrow q(y)).$$

As we can see in the above example, the standard prenex form conversion
turns a non-singular occurrence of a quantifier into an outermost $\forall$ while
preserving strong equivalence. Consequently, if a sentence contains no singular
occurrences of quantifiers, then the above result can be used to turn it into a
universal sentence. However, in the presence of a singular occurrence of a quantifier, such as $\exists x \, q(x)$ in (5.1), the standard prenex form conversion turns the occurrence into an outermost $\exists$, which is not allowed in logic programs. Below we consider how to handle such occurrences.

Obviously, if the Herbrand universe is finite, and if we are interested in Herbrand stable models (i.e., answer sets) only, quantified formulas can be rewritten as multiple disjunctions and conjunctions. We do not even need to consider turning the formula into prenex form. For example, for a formula

$$r \land \neg \exists x (p(x) \land q(x)) \rightarrow s$$

(5.3)

occurring in a theory whose signature contains \{1, \ldots, n\} as the only object constants (and no other function constants), if we replace $\exists x (p(x) \land q(x))$ with multiple disjunctions and then turn the resulting program with nested expression into a usual disjunctive program (Lifschitz et al., 1999), $2^n$ rules are generated. For instance, if $n = 3$, the resulting logic program is

$$s \leftarrow r, \text{not} \, p(1), \text{not} \, p(2), \text{not} \, p(3)$$

$$s \leftarrow r, \text{not} \, p(1), \text{not} \, p(2), \text{not} \, q(3)$$

$$s \leftarrow r, \text{not} \, p(1), \text{not} \, q(2), \text{not} \, p(3)$$

$$s \leftarrow r, \text{not} \, p(1), \text{not} \, q(2), \text{not} \, q(3)$$

$$s \leftarrow r, \text{not} \, q(1), \text{not} \, p(2), \text{not} \, p(3)$$

$$s \leftarrow r, \text{not} \, q(1), \text{not} \, p(2), \text{not} \, q(3)$$

$$s \leftarrow r, \text{not} \, q(1), \text{not} \, q(2), \text{not} \, p(3)$$

$$s \leftarrow r, \text{not} \, q(1), \text{not} \, q(2), \text{not} \, q(3).$$

However, this translation is not modular as it depends on the underlying domain; the multiple disjunctions or conjunctions need to be updated when the domain changes. More importantly, this method is not applicable if the language contains function constants of positive arity, as its Herbrand universe is infinite.
One may also consider introducing Skolem constants as in first-order logic, presuming that, for any sentence $F$ and its “Skolem form” $F'$, $SM[F; p]$ is satisfiable iff $SM[F'; p]$ is satisfiable. However, this method does not work.\footnote{Pearce and Valverde (2005) show that Skolemization works with $QN_5$, the monotonic basis of Quantified Equilibrium Logic, but as our example shows, this does not imply that Skolemization works with Quantified Equilibrium Logic.}

**Example 5** For formula

$$F = (\forall x p(x) \rightarrow q) \land \neg\exists x(q \land \neg p(x)),$$

$SM[F; q]$ is equivalent to the first-order sentence

$$(q \leftrightarrow \forall x p(x)) \land \exists x(q \land \neg p(x)),$$

which is unsatisfiable (the equivalence can be established using Theorems 3 and 11 from the work of Ferraris et al., 2011). Formula $F$ is strongly equivalent to its prenex form

$$\exists x \exists y ((p(x) \rightarrow q) \land \neg\neg(q \land \neg p(y))).$$  (5.4)

However, if we introduce new object constants $a$ and $b$ to replace the existentially quantified variables as in

$$F' = (p(a) \rightarrow q) \land \neg\neg(q \land \neg p(b)),$$

formula $SM[F'; q]$ is equivalent to

$$(q \leftrightarrow p(a)) \land (q \land \neg p(b)),$$

which is satisfiable.

Here we present a method of eliminating singular occurrences of quantifiers by introducing auxiliary predicates. Our idea is a generalization of the practice in logic programming that simulates negated existential quantification in the body of a
rule by introducing auxiliary predicates. For instance, in order to eliminate \( \exists \) in (5.3), we will introduce a new predicate constant \( p' \), and turn (5.3) into

\[
(r \land \neg p' \rightarrow s) \land \forall x(p(x) \land q(x) \rightarrow p'),
\]

which corresponds to the logic program

\[
s \leftarrow r, \text{not } p' \\
p' \leftarrow p(x), q(x).
\]

The models of \( \text{SM}[(5.3); p, q, r, s] \) are the same as those of \( \text{SM}[(5.5); p, q, r, s, p'] \) if we disregard \( p' \). This method does not involve grounding, so that the translation does not depend on the domain and is not restricted to Herbrand models. The method is formally justified by the following proposition.

**Proposition 2** Let \( F \) be a sentence of a signature \( \sigma \), let \( p \) be a finite list of distinct predicate constants, and let \( q \) be a new predicate constant that does not belong to \( \sigma \). Consider any non-strictly positive occurrence of \( \exists yG(y, x) \) in \( F \) that is contained in a subformula of \( F \) that is negative on \( p \), where \( x \) is the list of all free variables of \( \exists yG(y, x) \). Let \( F' \) be the formula obtained from \( F \) by replacing that occurrence with \( q(x) \). Then

\[
\text{SM}[F; p] \land \forall x[q(x) \leftrightarrow \exists yG(y, x)]
\]

is equivalent to

\[
\text{SM}[F' \land \forall x(G(y, x) \rightarrow q(x)); p, q].
\]

Proposition 2 tells us that \( \text{SM}[F; p] \) and \( \text{SM}[F' \land \forall x(G(y, x) \rightarrow q(x)); p, q] \) have the same models if we disregard the new predicate \( q \). Notice that \( F' \) does not retain the occurrence of \( \exists y \).

**Example 6** In formula (5.3), \( \exists x(p(x) \land q(x)) \) is contained in a negative formula (relative to any set of intensional predicates). In accordance with Proposition 2,
Any singular occurrence of a formula $\forall yG(y, x)$ that is contained in a subformula of $F$ that is negative on $\mathbf{p}$ can also be eliminated using Proposition 2 by first rewriting $\forall yG(y, x)$ as $\neg \exists y \neg G(y, x)$. Note that $\forall yG(y, x)$ is not strongly equivalent to $\neg \exists y \neg G(y, x)$, and in general the transformation may not necessarily preserve stable models. But the condition that $\forall yG(y, x)$ is negative on $\mathbf{p}$ ensures that it preserves $\mathbf{p}$-stable models.

Now we are ready to present our quantifier elimination method. We say that a formula $F$ is almost universal relative to $\mathbf{p}$ if every singular occurrence of $QxG$ in $F$ is contained in a subformula of $F$ that is negative on $\mathbf{p}$. For example, formula (5.3) is almost universal relative to any set of predicates because the only singular occurrence of $\exists x(p(x) \land q(x))$ in it is contained in $\neg \exists x(p(x) \land q(x))$, which is negative on any list of predicates. Formula $F$ in Example 5 is almost universal relative to $\{q\}$ because the singular occurrence of $\forall x p(x)$ is contained in the formula itself, which is negative on $\{q\}$, and the singular occurrence of $\exists x(q \land \neg p(x))$ is contained in $\neg \exists x(q \land \neg p(x))$, which is also negative on $\{q\}$.

The following procedure can be used to eliminate all (possibly nested) quantifiers in any almost universal sentence.

**Definition 1 (Translation ELIM-QUANTIFIERS)** Given a formula $F$, first prepend $\neg \neg$ to every maximal strictly positive occurrence of a formula of the form $\exists y H(y, x)$, and then repeat the following until there are no occurrences of quantifiers remaining: Select a maximal occurrence of a formula of the form $QyG(y, x)$ in $F$ where $Q$ is $\forall$ or $\exists$, and $x$ is the list of all free variables in $QyG(y, x)$.

---

3Recall the definition of a **negative formula** on $\mathbf{p}$ given in Chapter 4.

4The maximality is in terms of the subformula relation. That is, here we select a strictly positive occurrence of a formula of the form $\exists y H(y, x)$ that is not a strict subformula of the same form.
(a) If the occurrence of $Q_yG(y, x)$ in $F$ is non-singular in $F$, then set $F$ to be the formula obtained from $F$ by replacing the occurrence of $Q_yG(y, x)$ with $G(z, x)$ where $z$ is a new variable.

(b) If $Q$ is $\exists$ and the occurrence of $Q_yG(y, x)$ in $F$ is positive, then set $F$ to be

$$F' \land (G(y, x) \to p_G(x))$$

where $p_G$ is a new predicate constant and $F'$ is the formula obtained from $F$ by replacing the occurrence of $Q_yG(y, x)$ with $p_G(x)$.

(c) If $Q$ is $\forall$ and the occurrence of $Q_yG(y, x)$ in $F$ is negative, then set $F$ to be the formula obtained from $F$ by replacing the occurrence of $Q_yG(y, x)$ with $\neg\exists y \neg G(y, x)$.

We assume that the new predicate constants introduced by the translation do not belong to the signature of the input formula $F$. It is clear that this process terminates, and yields a formula that is quantifier-free. Since the number of times step (b) is applied is no more than the number of quantifiers in the input formula, and the new formulas added have the size polynomial to the input formula, it follows that the size of the resulting quantifier-free formula is polynomial in the size of the input formula.

The following theorem tells us that any almost universal sentence $F$ can be turned into the form $\forall x G$ where $G$ is a quantifier-free formula. For any (second-order) sentences $F$ and $G$ of a signature and any subset $\sigma$ of that signature, we say that $F$ is $\sigma$-equivalent to $G$, denoted by $F \equiv_{\sigma} G$, if the class of models of $F$ restricted to $\sigma$ is identical to the class of models of $G$ restricted to $\sigma$.

**Theorem 15** Let $F$ be a sentence of a signature $\sigma$, let $F'$ be the universal closure of the formula obtained from $F$ by applying translation ELIM-QUANTIFIERS, and...
let \( q \) be the list of new predicate constants introduced by the translation. If \( F \) is almost universal relative to \( p \), then \( \text{SM}[F; p] \) is \( \sigma \)-equivalent to \( \text{SM}[F'; p, q] \).

The statement of the theorem becomes incorrect if \( F \) is not required to be almost universal relative to \( p \). For instance, if ELIM-QUANTIFIERS is applied to \( \exists x p(x) \), it results in \( \neg\neg q \land (p(x) \rightarrow q) \). However, \( \text{SM}[\exists x p(x); p] \) is not \( \{p\}\)-equivalent to \( \text{SM}[\forall x (\neg\neg q \land (p(x) \rightarrow q)); p, q] \). The former means that \( p \) is a singleton. The latter is equivalent to \( q \land \forall x \neg p(x) \land (q \leftrightarrow \exists xp(x)) \), which is inconsistent.

5.2 Turning Quantifier-Free Formulas into the Syntax of Logic Programs

Cabalar et al. (2005) present two transformations to turn arbitrary propositional formulas into logic programs: one is vocabulary-preserving and the other introduces new atoms but is polynomial. Following is the vocabulary-preserving transformation shown in Section 3 of that paper.

- Left side rules:

\[
\begin{align*}
\top \land F \rightarrow G & \iff \{ F \rightarrow G \} \quad \text{(L1)} \\
\bot \land F \rightarrow G & \iff \emptyset \quad \text{(L2)} \\
\neg\neg F \land G \rightarrow H & \iff \{ G \rightarrow \neg F \lor H \} \quad \text{(L3)} \\
(F \lor G) \land H \rightarrow K & \iff \begin{cases} 
F \land H \rightarrow K \\
G \land H \rightarrow K
\end{cases} \quad \text{(L4)} \\
(F \rightarrow G) \land H \rightarrow K & \iff \begin{cases} 
\neg F \land H \rightarrow K \\
G \land H \rightarrow K \\
H \rightarrow F \lor \neg G \lor K
\end{cases} \quad \text{(L5)}
\end{align*}
\]
• Right side rules:

\[
\begin{align*}
F \rightarrow \bot \lor G & \mapsto \{F \rightarrow G\} \quad (R1) \\
F \rightarrow \top \lor G & \mapsto \emptyset \quad (R2) \\
F \rightarrow \neg G \lor H & \mapsto \{\neg G \land F \rightarrow H\} \quad (R3) \\
F \rightarrow (G \land H) \lor K & \mapsto \begin{cases} 
F \rightarrow G \lor K \\
F \rightarrow H \lor K 
\end{cases} \quad (R4) \\
F \rightarrow (G \rightarrow H) \lor K & \mapsto \begin{cases} 
G \land F \rightarrow H \lor K \\
\neg H \land F \rightarrow \neg G \lor K
\end{cases} \quad (R5)
\end{align*}
\]

Before applying this transformation to each formula on the lefthand side, it is assumed that the formula is already written in negation normal form, in which negation is applied to atoms only, by using the following transformation:

• Negation normal form conversion:

\[
\begin{align*}
\neg \top & \mapsto \bot \\
\neg \bot & \mapsto \top \\
\neg \neg \neg F & \mapsto \neg F \\
\neg (F \land G) & \mapsto \neg F \lor \neg G \\
\neg (F \lor G) & \mapsto \neg F \land \neg G \\
\neg (F \rightarrow G) & \mapsto \neg \neg F \land \neg G
\end{align*}
\]

According to Cabalar et al. (2005), successive application of the rewriting rules above turn any propositional formula into a disjunctive logic program. This result can be simply extended to turn any quantifier-free formula into a logic program.

As noted by Cabalar et al. (2005), this translation may involve an exponential blowup in size, and Theorem 1 from their paper shows that indeed
there is no vocabulary-preserving polynomial time algorithm to convert general propositional theories under the stable model semantics into disjunctive logic programs. Alternatively, one can use another translation from the same paper, which is linear in size but involves auxiliary atoms and is more complex.

5.3 F2LP: Turning Formulas in the First-Order Stable Model Semantics into the Syntax of ASP

Using the translations discussed in the previous sections, we introduce translation F2LP that turns an almost universal formula into a logic program.

**Definition 2** [Translation F2LP]

1. Given a formula $F$ and a list of intensional predicates $p$, apply translation ELIM-QUANTIFIERS (Definition 1) to $F$;

2. Add choice formulas $\left(q(x) \lor \neg q(x)\right)$ for all non-intensional predicates $q$.

3. Turn the resulting quantifier-free formula into a logic program by applying the translation from (Cabalar et al., 2005, Section 3), which was reviewed in Chapter 5.2.

Due to the third step, this transformation may involve an exponential blowup in size. One can obtain a polynomial time translation by replacing Step 3 with an alternative translation given in (Cabalar et al., 2005, Section 4).

The following theorem asserts the correctness of translation F2LP.

**Theorem 16** Let $F$ be a sentence of a signature $\sigma$, let $p$ be a list of intensional predicates, and let $F'$ be the FOL representation of the program obtained from $F$ by applying translation F2LP with $p$ as intensional predicates. If $F$ is almost universal relative to $p$, then $SM[F; p]$ is $\sigma$-equivalent to $SM[F' \land \text{False}(p \setminus \text{pr}(F'))]$. 
Example 7  Consider one of the domain independent axioms in the discrete event calculus (DEC5 axiom):

\[ \text{HoldsAt}(f, t) \land \neg \text{ReleasedAt}(f, t+1) \land \neg \exists e (\text{Happens}(e, t) \land \text{Terminates}(e, f, t)) \rightarrow \text{HoldsAt}(f, t+1). \]  

(5.7)

Step 1 of translation F2LP introduces the formula

\[ \text{Happens}(e, t) \land \text{Terminates}(e, f, t) \rightarrow q(f, t), \]

and replaces (5.7) with

\[ \text{HoldsAt}(f, t) \land \neg \text{ReleasedAt}(f, t+1) \land \neg q(f, t) \rightarrow \text{HoldsAt}(f, t+1). \]

Step 3 turns these formulas into rules

\[ q(f, t) \leftarrow \text{Happens}(e, t), \text{Terminates}(e, f, t) \]

\[ \text{HoldsAt}(f, t+1) \leftarrow \text{HoldsAt}(f, t), \text{not ReleasedAt}(f, t+1), \text{not } q(f, t). \]

System F2LP

System F2LP is an implementation of translation F2LP, which turns a first-order formula into the languages of LPARSE and GRINGO. The system can be downloaded from its home page

http://reasoning.eas.asu.edu/f2lp/.

First-order formulas can be encoded in F2LP using the following ASCII representation for the quantifiers and connectives.

<table>
<thead>
<tr>
<th>Symbol</th>
<th>¬</th>
<th>¬</th>
<th>∧</th>
<th>∨</th>
<th>→</th>
<th>⊥</th>
<th>T</th>
<th>∀xyz</th>
<th>∃xyz</th>
</tr>
</thead>
<tbody>
<tr>
<td>ASCII</td>
<td>-</td>
<td>~</td>
<td>&amp;</td>
<td>l</td>
<td>-&gt;</td>
<td>false</td>
<td>true</td>
<td>![X,Y,Z]:</td>
<td>?[X,Y,Z]:</td>
</tr>
</tbody>
</table>
The system also allows extended rule form $F \leftarrow G$ where $F$ and $G$ are first-order formulas. In this case, \texttt{not} is used to represent $\neg$, $-$ is used to represent $\sim$, and $\leftarrow$ is used to represent $\leftarrow$.

The usual LPARSE and GRINGO rules (which have rule arrow $: -$) are also allowed in F2LP. Such rules are simply copied to the output. The program returned by F2LP can be passed to ASP grounders and solvers that accept LPARSE and GRINGO languages.

For example, formula $\exists x y p(x, y) \rightarrow \forall z (\neg q(z) \land r(z))$ can be represented as

$\text{?}[X,Y]: p(X,Y) \rightarrow \text{!}[Z]: (\neg q(Z) \land r(Z))$. 

Here, the dot(.) indicates the end of the formula. Each formula should end with a dot(.)

\textbf{Example 8} Consider $F = \forall x p(x, y) \rightarrow \forall x q(x)$.

where $p$ is extensional. Here $y$ is assumed to be universally quantified. This is represented as

$\text{!}[X]: p(X,Y) \rightarrow \text{!}[X]: q(X)$. 

\texttt{extensional} \texttt{p(X,Y)}.

\textit{in F2LP syntax. F2LP turns this formula into}

$q(_{NV_1}) :$ \texttt{not} \texttt{new_pred_1(Y)}.

$\{p(X,Y)\}$. 

\texttt{new_pred_1(Y)} :\texttt{not} \texttt{p(X,Y)}.
Here, \_NV\_1 and \_new\_pred\_1 are the new variable and new predicate introduced respectively. Further, \{p(X, Y)\} is the choice rule introduced since \(p\) is extensional.

**Example 9**  *The input*

\![X]: p(X,Y) -> !X: q(X) & r.

\#extensional p(X,Y).

*is turned to*

q(_NV_1) :- not _new_pred_1(Y).

r :- not _new_pred_1(Y).

\{p(X,Y)\}.

_new_pred_1(Y) :- not p(X,Y).

**Example 10**  *The input*

p(X,Y) -> -q(X) \mid X = Y.

*is turned to*

:- X!=Y,\{not q(X)\}0,p(X,Y).

This example shows how F2LP handles negation and equality in the head. F2LP turns negation in the head to double negation in the body (according to LPARSE and GRINGO languages, \{not q(X)\}0 represents not not q(X). This is the same as in RASPL-1 (Chapter 4.2)).

In addition to usual first-order formulas, F2LP also allows the choice construct and aggregate formulas (Lee & Meng, 2009). Aggregate formulas are
formulas built from normal atomic formulas (including equality) and aggregate expressions using the standard connectives and quantifiers in first-order logic. In other words, aggregate expressions are treated as atomic formulas. F2LP currently supports both GRINGO and DLV aggregates. A detailed manual of F2LP can be found from its homepage.

**Example 11** *The input*

\[
\begin{align*}
&\text{s(Y) & not 2\{t(X,Z,Z):s(Z)\} -> \{p(X):q(X)\} & r(Y).} \\
&\text{#sum[t(X,Y,Z):r(Z):q(Y),s(X)\}5 | s(X) -> \{p(X)\}.} \\
&\text{#count\{}X:p(X,Y)\}\geq 5 | s(Y) -> q(Y).}
\end{align*}
\]

is turned to

\[
\begin{align*}
&\{p(X):q(X)\} :- s(Y), not 2\{t(X,Z,Z):s(Z)\}. \\
r(Y) :- s(Y), not 2\{t(X,Z,Z):s(Z)\}. \\
&\{p(X)\} :- \#sum[t(X,Y,Z):r(Z):q(Y),s(X)\}5. \\
&\{p(X)\} :- s(X). \\
&q(Y) :- \#count\{}X:p(X,Y)\}\geq5. \\
&q(Y) :- s(Y). \\
\end{align*}
\]

As an example of the extended rule form representation, consider the following input:

\[
!\{X\}: q(X) & r <- not !\{X\}: p(X,Y). \\
#extensional p(X,Y).
\]

When the above input is given to F2LP, it produces the following output:

\[
q(_{NV_2}) :- not p(_{NV_1},Y).
\]
r :- not p(_NV_1,Y).
{p(X,Y)}.

where _NV_1 and _NV_2 are the new variables introduced.

5.4 Related Work

The idea of the translation F2LP is similar to the one independently given by Cabalar (2009) that eliminates existential quantifiers in the scope of negation in the body of a rule. The difference is that our translation applies to the larger class of almost universal formulas and also differentiates between intensional and extensional predicates. Zhang et al. (2011) introduce a translation that turns arbitrary first-order formulas into logic programs, but this work is limited to finite structures only. On the other hand, our translation works for almost universal formulas only, but is not limited to finite structures.

5.5 Relevance to Later Chapters

Translation F2LP is used in the later chapters to reformulate the event calculus, the situation calculus, and TAL in ASP. While the complete reformulations are provided in the respective chapters on each of the formalisms, we will briefly discuss the reformulation of the event calculus here. As we will see in Chapter 7.2, an event calculus description can be turned into the following formula by using the result on canonical formulas (Chapter 3.3) and the splitting theorem (Chapter 4.1):

\[ \text{SM}[\Sigma \land \Delta \land \Theta \land \Xi ; \text{Initiates, Terminates, Releases, Happens, } Ab_1, \ldots, Ab_n]. \]

Translation F2LP is used to turn the above formula into the syntax of ASP. As a result, system F2LP can be used to compute event calculus descriptions using answer set solvers.
5.6 Proofs

Proof of Theorem 14

One can verify this by checking that for any formula $F$, and the formula $F'$ obtained from $F$ by applying one of the prenex form conversion rules given in Section 6.3.1 of (Pearce & Valverde, 2005), formula

$$u \leq p \rightarrow (F^*(u) \leftrightarrow F'^*(u))$$

is logically valid where $p$ is any list of predicate constants and $u$ is the corresponding list of predicate variables.

$\square$

Proof of Proposition 2

Lemma 8 (Ferraris et al., 2011, Lemma 6) Formula

$$u \leq p \rightarrow ((\neg F)^*(u) \leftrightarrow \neg F)$$

is logically valid.

Lemma 9 Let $F$ be a formula, let $p$ be a list of distinct predicate constants, let $G$ be a subformula of $F$ and let $G'$ be any formula that is classically equivalent to $G$. Let $F'$ be the formula obtained from $F$ by substituting $G'$ for $G$. If the occurrence of $G$ is in a subformula of $F$ that is negative on $p$ and the occurrence of $G'$ is in a subformula of $F'$ that is negative on $p$, then

$$SM[F; p] \leftrightarrow SM[F'; p]$$

is logically valid.

Proof. Let $F\neg\neg$ be the formula obtained from $F$ by prepending $\neg\neg$ to $G$, and let $(F')\neg\neg$ be the formula obtained from $F'$ by prepending $\neg\neg$ to $G'$. By the Theorem
on Double Negations (Theorem 13), the following formulas are logically valid.

\[
\begin{align*}
\text{SM}[F; p] & \leftrightarrow \text{SM}[\neg\neg F; p], \\
\text{SM}[F'; p] & \leftrightarrow \text{SM}[(F')\neg\neg; p].
\end{align*}
\]

From Lemma 8, it follows that

\[
(u \leq p \land (G \leftrightarrow G')) \rightarrow ((\neg\neg)^*(u) \leftrightarrow ((F')\neg\neg)^*(u))
\]

is logically valid, where \( u \) is a list of predicate variables corresponding to \( p \).

Consequently,

\[
\text{SM}[\neg\neg F; p] \leftrightarrow \text{SM}[(F')\neg\neg; p]
\]

is logically valid.

\[\square\]

**Proof of Proposition 2.** In formula

\[
\text{SM}[F' \land \forall xy(G(y, x) \rightarrow q(x)); p, q],
\]

(5.8)

clearly, \( F' \) is negative on \( q \) and \( \forall xy(G(y, x) \rightarrow q(x)) \) is negative on \( p \). Let \( H \) be any subformula of \( F \) that is negative on \( p \) and contains the occurrence of \( \exists y G(y, x) \). Consider two cases.

- **Case 1:** the occurrence of \( \exists y G(y, x) \) in \( H \) is not strictly positive. Thus the dependency graph (Chapter 3.2) of \( F' \land \forall xy(G(y, x) \rightarrow q(x)) \) relative to \( \{p, q\} \) has no incoming edges into \( q \).

- **Case 2:** the occurrence of \( \exists y G(y, x) \) in \( H \) is strictly positive. Since \( H \) is negative on \( p \), \( \exists y G(y, x) \) is negative on \( p \) as well, so that the dependency graph of \( F' \land \forall xy(G(y, x) \rightarrow q(x)) \) relative to \( \{p, q\} \) has no outgoing edges from \( q \).
Therefore, every strongly connected component in the dependency graph belongs to either \( p \) or \( \{q\} \). Consequently, by Theorem 12, (5.8) is equivalent to

\[
\text{SM}[F'; p] \land \text{SM}[\forall x y (G(y, x) \rightarrow q(x)); q] \tag{5.9}
\]

Since \( \exists y G(y, x) \) is negative on \( q \), formula \( \forall x y (G(y, x) \rightarrow q(x)) \) is tight on \( \{q\} \). By Theorem 3, (5.9) is equivalent to

\[
\text{SM}[F'; p] \land \forall x (\exists y G(y, x) \leftrightarrow q(x)). \tag{5.10}
\]

By Lemma 9, it follows that (5.10) is equivalent to

\[
\text{SM}[F; p] \land \forall x (\exists y G(y, x) \leftrightarrow q(x)).
\]

Consequently, the claim follows. \( \square \)

Proof of Theorem 15

It is clear that the algorithm terminates and yields a quantifier-free formula \( K \). We will prove that \( \text{SM}[F; p] \) is \( \sigma \)-equivalent to \( \text{SM}[\forall x K; p \cup q] \) where \( x \) is the list of all (free) variables of \( K \).

Let \( F^{\neg\neg} \) be the formula obtained from the initial formula \( F \) by prepending double negations in front of every maximal strictly positive occurrence of formulas of the form \( \exists y G(x, y) \). Since \( F \) is almost universal relative to \( p \), such an occurrence is in a subformula of \( F \) that is negative on \( p \). Thus by the Theorem on Double Negations (Theorem 13), \( \text{SM}[F; p] \) is equivalent to \( \text{SM}[F^{\neg\neg}; p] \). Note that \( F^{\neg\neg} \) contains no strictly positive occurrence of formulas of the form \( \exists y G(x, y) \).

For each iteration, let us assume that the formula before the iteration is

\[
H_0 \land \cdots \land H_n
\]

where \( H_0 \) is transformed from \( F^{\neg\neg} \) by the previous iterations, and each \( H_i \) (\( i > 0 \)) is a formula of the form \( G(x, y) \rightarrow p_G(x) \) that is introduced by Step (b). Initially \( H_0 \)
is $F^\neg\neg$ and $n = 0$. Let $r_0$ be $p$, and let $r_i$ be each $p_G$ for $H_i$ ($i > 0$). By induction we can prove that

(i) every positive occurrence of formulas of the form $\exists y G(x, y)$ in $H_i$ is not strictly positive, and is in a subformula of $H_i$ that is negative on $r_i$;

(ii) every negative occurrence of formulas of the form $\forall y G(x, y)$ in $H_i$ is in a subformula of $H_i$ that is negative on $r_i$.

We will prove that if Step (a) or Step (c) is applied to turn $H_k$ into $H'_k$, then

$$\text{SM} [\forall x_0 H_0; r_0] \land \cdots \land \text{SM} [\forall x_n H_n; r_n]$$

(5.11)

is equivalent to

$$\text{SM} [\forall x'_0 H'_0; r_0] \land \cdots \land \text{SM} [\forall x'_n H'_n; r_n]$$

(5.12)

where $H'_j = H_j$ for all $j$ different from $k$, and $x_i$ ($i \geq 0$) is the list of all free variables of $H_i$, and $x'_i$ ($i \geq 0$) is the list of all free variables of $H'_i$.

Indeed, Step (a) is a part of prenex form conversion, which preserves strong equivalence (Theorem 14). So it is clear that (5.11) is equivalent to (5.12).

When Step (c) is applied to turn (5.11) into (5.12), since $\forall y H(x, y)$ is in a subformula of $H_k$ that is negative on $r_k$, the equivalence between (5.11) and (5.12) follows from Lemma 9.

When Step (b) is applied to turn $H_k$ into $H'_k$ and introduces a new conjunctive term $H'_{n+1}$, formula (5.11) is $(\sigma, r_1, \ldots, r_n)$-equivalent to

$$\text{SM} [\forall x'_0 H'_0; r_0] \land \cdots \land \text{SM} [\forall x'_n H'_n; r_n] \land \text{SM} [\forall x'_{n+1} H'_{n+1}; r_{n+1}]$$

(5.13)

by Proposition 2 due to condition (i).

Let

$$H'_0 \land \cdots \land H'_m$$

(5.14)
be the final quantifier-free formula where $H''_0$ is transformed from $F^{\neg\neg}$. By the induction, it follows that $\text{SM}[F; p]$ is $\sigma$-equivalent to

$$\text{SM}[\forall x''_0 H''_0; r_0] \land \cdots \land \text{SM}[\forall x''_m H''_m; r_m], \quad (5.15)$$

where each $x''_i$ ($0 \leq i \leq m$) is the list of all free variables of $H''_i$.

Since every non-strictly positive occurrence of new predicate $r_i$ ($i > 0$) in any $H''_j$ ($0 \leq j \leq m$) is positive, there is no incoming edge into $r_i$ in the dependency graph of (5.14) relative to $r_0, r_1, \ldots, r_m$. Consequently, every strongly connected component of the dependency graph belongs to one of $r_i$ ($i \geq 0$). Moreover, it is clear that each $H''_i$ ($i \geq 0$) is negative on every $r_j$ for $j \neq i$. (In the case of $H''_0$, recall that the occurrence of $r_j$ for any $j > 0$ is not strictly positive since $F^{\neg\neg}$, from which $H''_0$ is obtained, contains no strictly positive occurrence of formulas of the form $\exists y G(x, y)$.) Thus by the splitting theorem (Theorem 12), formula (5.15) is equivalent to

$$\text{SM}[\forall x''_0 H''_0 \land \cdots \land \forall x''_m H''_m; r_0 \cup \cdots \cup r_m]. \quad (5.16)$$

□

Proof of Theorem 16

We use the notations introduced in the proof of Theorem 15. By Theorem 15, $\text{SM}[F; p]$ is $\sigma$-equivalent to (5.16) and, by Theorem 6, (5.16) is equivalent to

$$\text{SM}[\forall x''_0 H''_0 \land \cdots \land \forall x''_m H''_m \land \text{Choice}(\sigma^{\text{pred}} \setminus p); \sigma^{\text{pred}} \cup r_1 \cup \cdots \cup r_m] \quad (5.17)$$

($r_0$ is $p$) where $\sigma^{\text{pred}}$ is the set of all predicate constants in signature $\sigma$. It follows from Proposition 3 from (Cabalar et al., 2005) that (5.17) is equivalent to

$$\text{SM}[\forall x''_0 H'''_0 \land \cdots \land \forall x''_m H'''_m \land \text{Choice}(\sigma^{\text{pred}} \setminus p); \sigma^{\text{pred}} \cup r_1 \cup \cdots \cup r_m] \quad (5.18)$$

where $H'''_i$ is obtained from $H''_i$ by applying the translation from (Cabalar et al., 2005, Section 3) (reviewed in Chapter 5.2) that turns a quantifier-free formula into
a set of rules. It is easy to see that $F'$ is the same as the formula

$$\forall x'_0 H'_0 \land \cdots \land \forall x'_m H'_m \land \text{Choice}(\sigma^{\text{pred}} \setminus p)$$

and $\sigma^{\text{pred}} \cup r_1 \cup \cdots \cup r_m$ is the same as $p \cup \text{pr}(F')$, so that (5.18) can be written as

$$\text{SM}\left[F'; \ p \cup \text{pr}(F')\right],$$

which is equivalent to

$$\text{SM}\left[F' \land \text{False}(p \setminus \text{pr}(F'))\right].$$

by Proposition 1.
Chapter 6

SAFETY

The safety property was studied in datalog as a condition under which the set of answers for a given query is finite (see, for example, (Ullman, 1985; Zaniolo, 1986; Ramakrishnan, Bancilhon, & Silberschatz, 1987; Krishnamurthy, Ramakrishnan, & Shmueli, 1996)). Safety thus guarantees the decidability of query answering. The study of the safety property has been carried over to ASP (see, for example, (McCain & Turner, 1994)) and it plays an important role in the design of answer set solvers. According to the traditional definition of safety in ASP, a rule in a program is safe if every variable occurring in it also occurs in the positive part of the body. A program is safe if all the rules in it are safe. Answer set solvers accept only safe rules as input. There are a couple of reasons for this.

The first reason is mainly from a semantic point of view but is also related to decidability. Consider the following unsafe program:

\[
p(x) \leftarrow \text{not } q(y)
\]

\[
q(a)
\]

This program is not safe since the first rule is not safe (\(x\) and \(y\) do not occur in the positive body). Recall that the traditional way to compute the answer sets of programs with variables involves grounding the program with the Herbrand universe of the signature obtained from the program. In this case, the signature obtained from the program is \(\{p/1, q/1, a\}\) and the program has one answer set: \(\{q(a)\}\). However, if we extend the signature by an object constant \(b\) and consider the additional object constant for grounding, we get \(\{q(a), p(a), p(b)\}\) as the answer set of the resulting ground program. This implies that answer sets of a program with variables actually depend on the signature of the program. However, we only consider the signature that can be obtained from the program in order to
compute the answer sets. Safety actually justifies this choice of the signature since the answer sets of a safe program depend only on the constants that occur in the program. This in turn implies that safety not only enables domain-independent reasoning but also guarantees decidability in the absence of function constants.

The second reason is from the point of view of computational efficiency. The safety property is used in the answer set solvers to reduce the size of the ground program and also to enhance the speed of grounding. For example, consider the following safe program:

\[ p(x) \leftarrow \text{not } q(y), r(x, y) \]
\[ r(a, b) \]

The ground program generated by answer set solvers does not include rules where \( x \) is substituted with \( b \) and \( y \) is substituted with \( a \) (in the absence of \( r(x, y) \) in the first rule, both \( x \) and \( y \) need to be substituted with \( a \) and \( b \)).

The definition of safety can be straightforwardly extended to disjunctive programs, and Bria, Faber, and Leone (2008) extended safety to a special class of programs with nested expressions (Lifschitz et al., 1999) called Normal Form Nested Programs. However, these extensions are not general enough to cover programs with aggregates. Though there has been some work done in extending safety to programs with aggregates, these extensions impose more stringent conditions than necessary. For example, the following safe rule is not covered by the definition of safety in (Faber et al., 2004):

\[ p(x) \leftarrow \#\text{count}\{y : q(x, y)\} \geq 2 \] (6.1)

In this chapter, we present a generalization of safety to formulas under the first-order stable model semantics, and show how the generalization can be used to define safety for RASPL-1 programs (Chapter 4.2), which allow representation
of the count aggregate. We discuss the related work at the end of the chapter.

Several parts of this chapter are also presented in (Lee et al., 2008a; Lee, Lifschitz, & Palla, 2008b, 2009).

6.1 Generalization of Safety

We consider first-order formulas that may contain object constants and equality but no function constants of arity $> 0$. The definition of a safe formula generalizes the safety condition to arbitrary sentences in prenex form. The assumption that the formula is in prenex form is not a significant limitation in view of Theorem 14 (Chapter 5.1), which implies that all steps involved in the standard process of converting a formula to prenex form are strongly equivalent transformations.

To every quantifier-free formula $F$ we assign a set $RV(F)$ of its restricted variables as follows:

- For an atomic formula $F$,
  - if $F$ is an equality between two variables then $RV(F) = \emptyset$;
  - otherwise, $RV(F)$ is the set of all variables occurring in $F$;
- $RV(\bot) = \emptyset$;
- $RV(F \land G) = RV(F) \cup RV(G)$;
- $RV(F \lor G) = RV(F) \cap RV(G)$;
- $RV(F \rightarrow G) = \emptyset$.

We say that a variable $x$ is restricted in $F$ if $x$ belongs to $RV(F)$. For instance, consider a rule of the form

$$A \leftarrow A_1, \ldots, A_n, \text{not } A_{n+1}, \ldots, \text{not } A_m \quad (6.2)$$

\footnote{Some clauses of this definition are similar to parts of the definition of an allowed formula in (Topor & Sonenberg, 1988).}
which can be viewed as

\[ A_1 \land \cdots \land A_n \land \neg A_{n+1} \land \cdots \land \neg A_m \rightarrow A. \]

A variable \( x \) is restricted in the body of the rule iff it occurs in the positive body.

Consider a sentence \( F \) in prenex form:

\[ Q_1 x_1 \cdots Q_n x_n M \]

(\( Q_i \) is \( \forall \) or \( \exists \); \( x_1, \ldots, x_n \) are distinct variables; the matrix \( M \) is quantifier-free).

We say that \( F \) is semi-safe if every occurrence of each of the variables \( x_i \) in \( M \) is contained in a subformula \( G \rightarrow H \) where \( x_i \) is restricted in \( G \). For example, consider

\[ \forall x \exists y (p(x) \land \neg q(y) \rightarrow r(x)). \]

(6.4)

This formula is semi-safe since both the occurrences of \( x \) in the matrix belong to the matrix itself (which is an implication) and \( x \) is restricted in the antecedent of the matrix, and the only occurrence of \( y \) in the matrix belongs to the implication \( q(y) \rightarrow \bot \) and \( y \) is restricted in the antecedent of the implication. We identify a formula containing free variables with its universal closure so that a rule (6.2) is semi-safe iff every variable occurring in the head also occurs in the positive body.

Formula

\[ \forall x \exists y (p(x) \land \neg q(y) \rightarrow r(x, y)) \]

(6.5)

is not semi-safe since the strictly positive occurrence of \( y \) in the matrix is not restricted in antecedent of the matrix (\( \text{RV}(\neg q(x)) = \emptyset \)).

The definition of a safe formula adds an additional restriction to the definition of a semi-safe formula. We say a sentence (6.3) is safe if every occurrence of each of the variables \( x_i \) in \( M \) is contained in a subformula \( G \rightarrow H \) that satisfies two conditions:

\(^2\text{Recall that we treat } \neg F \text{ as shorthand for } F \rightarrow \bot.\)
(a) the subformula is positive in $M$ if $Q_i$ is $\forall$, and negative in $M$ if $Q_i$ is $\exists$; and

(b) $x_i$ is restricted in $G$.

Consider the sentence (6.4). This sentence is safe because of the following reasons. Both the occurrences of $x$ in the matrix belong to the matrix itself (which is positive in itself) and $x$ is restricted in the antecedent of the matrix. The only occurrence of $y$ in the matrix belongs to the implication $q(y) \rightarrow \bot$, which is negative in the matrix, and $y$ is restricted in the antecedent of the implication.

Now, consider a rule (6.2). If every variable occurs in the positive body, then every occurrence of every variable belongs to the rule and every variable is restricted in the body. So, such a rule is safe. On the other hand, consider a variable that occurs only in the negative body. Clearly, that variable is not restricted in the body. So, any rule with such a variable is not safe. So, a rule (6.2) is safe iff every variable occurring in it also occurs in the positive body.

Similarly, one can check that

$$\forall x (\neg p(x) \lor \neg q(x) \rightarrow r)$$

is semi-safe but not safe.

Since the prenex form transformation is strongly equivalent, we can consider a formula to be safe if its prenex form is safe. For instance, the formula

$$p(a) \land \forall x (p(x) \land \neg \exists y q(y) \rightarrow r(x))$$

is safe since

$$\forall x \exists y (p(a) \land (p(x) \land \neg q(y) \rightarrow r(x)))$$

is safe.

In the remaining part of the section, we present some interesting properties of safe sentences, which ensure domain-independent and decidable reasoning.
The Small Predicate Property

We say that a stable model of a sentence $F$ has the small predicate property if, for every predicate constant $p_i$, if the relation represented by it holds for a tuple of arguments, then each member of the tuple is represented by an object constant occurring in $F$. To make this idea precise, we will use the following notation: for any finite set $c$ of object constants, $\text{in}_c(x_1, \ldots, x_m)$ stands for the formula

$$\bigwedge_{1 \leq j \leq m} \bigvee_{c \in c} x_j = c.$$

The small predicate property can be expressed by the conjunction of the sentences

$$\forall x (p_i(x) \rightarrow \text{in}_c(x))$$

for all predicate constants $p_i$ occurring in $F$, where $x$ is a list of distinct variables. We will denote this sentence by $\text{SPP}_c$. By $c(F)$ we denote the set of all object constants occurring in $F$.

**Proposition 3** For any semi-safe sentence $F$, $\text{SM}[F]$ entails $\text{SPP}_{c(F)}$.

For instance, if $F$ is (6.6), then the proposition asserts that $\text{SM}[F]$ entails

$$\forall x (p(x) \rightarrow x = a) \land \forall x (q(x) \rightarrow x = a).$$

Characterizing the Stable Models of a Safe Sentence

Proposition 3 seems to suggest that the stable models of a safe sentence $F$ are closely related to the stable models of the sentence obtained by grounding $F$ with the object constants occurring in it. In order to show that this is indeed the case, we define $\text{Ground}_c[F]$ for any safe sentence $F$ in prenex form as follows. If $F$ is quantifier-free, then $\text{Ground}_c[F]$ is $F$. Otherwise,
\[
\text{Ground}_c[\forall x F(x)] = \bigwedge_{c \in c} \text{Ground}_c[F(c)],
\]

\[
\text{Ground}_c[\exists x F(x)] = \bigvee_{c \in c} \text{Ground}_c[F(c)].
\]

**Theorem 17** For any safe sentence \( F \) and any nonempty finite set \( c \) of object constants containing \( c(F) \), \( SM[\text{Ground}_c[F]] \) is equivalent to \( SM[F] \).

This theorem asserts that the stable models of a safe sentence \( F \) are the stable models of the variable-free sentence obtained by grounding \( F \) with respect to the object constants occurring in \( F \). This result also establishes the domain-independence of the answer sets of safe formulas, i.e., adding object constants to the signature obtained from the formula does not change the Herbrand stable models. Further, the above theorem also enables us to characterize the stable models of a safe sentence by a propositional formula under the unique name assumption (UNA).

For example, consider the safe formula (6.6). The above theorem asserts that \( SM[F; p, q, r] \) is equivalent to

\[
SM[p(a) \land (p(a) \land \neg q(a) \to r(a)); p, q, r].
\]

Since there is only one object constant in \( F \), UNA holds by default. So, by treating the formula under \( SM \) as a propositional formula, it follows from the relationship of \( SM \) to completion (Theorem 3, Chapter 3.2) that the models of the above formula can be represented by the models of the propositional formula

\[
p(a) \land \neg q(a) \land (p(a) \land \neg q(a) \leftrightarrow r(a)).
\]

So, questions such as “does \( SM[F; pr(F)] \models \forall x \neg q(x)? \)” can be answered by simply computing the models of the above propositional formula. In other words,
entailment checking w.r.t safe formulas reduces to the problem of propositional satisfiability.

We now show that the stable models of a safe sentence can be characterized by a first-order sentence.

**Theorem 18** For every safe sentence $F$ there exists a variable-free formula $G$ such that $SM[F]$ is equivalent to $G \land SPP_c(F)$.

**Extending a Stable Model**

In the beginning of the chapter, we mentioned that the answer sets of a safe program do not change upon adding object constants to the signature obtained from the program. This result is extended to safe formulas by Theorem 17. Here, we prove a similar result by considering first-order stable models instead of answer sets.

Let $I$ be an interpretation of a set of object and predicate constants, and let $X$ be a superset of the universe of $I$. By the extension of $I$ to $X$ we mean the interpretation of the same constants with the universe $X$ such that each object constant represents the same object under both interpretations, and each predicate constant represents the same set of tuples.

**Theorem 19** For any safe sentence $F$, any interpretation $I$ of the object and predicate constants from $F$, and any superset $X$ of the universe of $I$, the extension of $I$ to $X$ is a stable model of $F$ iff $I$ is a stable model of $F$.

6.2 Safety for RASPL-1

In view of the reductive semantics of RASPL-1 (Chapter 4.2), this definition of safety can be used to define safety for RASPL-1 programs, thus overcoming some of the limitations with the earlier definitions and contributing to the design of
answer set solvers. We adapt the definition of safety provided above to RASPL-1 programs as follows.

Recall that an RASPL-1 program is a finite set of rules of the form

$$A_1; \ldots; A_l \leftarrow E_1, \ldots, E_m, \text{not } E_{m+1}, \ldots, \text{not } E_{n} \quad (6.7)$$

where each $A_i$ is an atom, semi-colon ($;$) represents disjunction, and each $E_i$ is an aggregate expression of the form

$$b \{x : F_1, \ldots, F_k\} \quad (6.8)$$

($k \geq 1$), where $b$ is a positive integer ("the bound"), $x$ is a list of variables (possibly empty), and each $F_i$ is an atom possibly preceded by not. Since comma (,) represents conjunction, we can view (6.8) as

$$b \{x : F\} \quad (6.9)$$

where $F$ stands for $F_1 \land \cdots \land F_k$.

We say that an aggregate expression $b \{x : F\}$ is allowed if every member of $x$ is restricted in $F$. For instance, $2 \{x : p(x, y)\}$ is allowed; $2 \{x : p(y)\}$ and $2 \{x : \text{not } p(x, y)\}$ are not allowed.

We say that a variable $v$ is restricted in an aggregate expression $b \{x : F\}$ if $v$ is restricted in $F$ and does not belong to $x$. For instance, $y$ is restricted in $2 \{x : p(x, y)\}$ and in $2 \{x : p(y)\}$, but is not restricted in $2 \{x : \text{not } p(x, y)\}$.

A variable $v$ is free in a rule (6.7) if

- $v$ occurs in the head $A_1; \ldots; A_l$ of the rule, or
- the body $E_1, \ldots, \text{not } E_n$ of the rule contains an aggregate expression $b \{x : F\}$ such that $v$ occurs in $F$ and does not belong to $x$. 

81
A rule (6.7) is safe if

- each aggregate expression in its body is allowed, and
- each of its free variables is restricted in one of the aggregate expressions $E_1, \ldots, E_m$.

A RASPL-1 program is safe if each of its rules is safe. For example, the RASPL-1 program (4.17) that computes cliques of size greater than or equal to $n$ is safe and is accepted by some answer set solvers. However, any program containing (6.1)$^3$ or the rule$^4$

$$ q \leftarrow \text{not } 1\{\text{not } p(x)\} $$

is not accepted by answer set solvers as they consider them unsafe. On the other hand, the definition of safety presented here asserts that these rules are safe and answer set solvers can be extended to accept such rules.

As an example of an unsafe rule, consider

$$ p(x) \leftarrow 2\{x : q(x)\}.$$ 

This rule is not safe since the free variable $x$ is not restricted in $2\{x : q(x)\}$.

The following theorem states that the answer sets of a safe RASPL-1 program do not change upon adding object constants to the signature obtained from the program.

**Theorem 20** Let $\Pi$ be a safe RASPL-1 program containing at least one object constant, and let $F$ be its FOL-representation. For any signature $\sigma$ obtained by adding object constants to $\sigma(F)$, an Herbrand interpretation of $\sigma$ satisfies $SM[F]$ iff it is an answer set of $\Pi$.

$^3$This is not a RASPL-1 rule but can be straightforwardly rewritten as one.

$^4$Such rules are quite useful when we want to compute answer sets of arbitrary formulas.
6.3 Related Work

The definition of safety by Cabalar, Pearce, and Valverde (2009) generalizes our
definition provided above. We review here a slightly different version of their
definition. We say that a formula (6.3) is CPV-semi-safe if every strictly positive
occurrence of each of the variables $x_i$ in $M$ belongs to a subformula $G \rightarrow H$
where $x_i$ is restricted in $G$. It is easy to see that any sentence that is semi-safe
according to our definition is also CPV-semi-safe. For example, formula (6.4),
which is semi-safe according to our definition, is also CPV-semi-safe. Since the
definition of a CPV-semi-safe formula imposes restrictions on only the strictly
positive occurrences of variables, any formula in which no variable occurs strictly
positively is trivially CPV-semi-safe. For example, the formula

$$q(x) \lor r(y) \rightarrow r$$

is CPV-semi-safe, but is not semi-safe according to our definition. Formula (6.5) is
not semi-safe according to both the definitions since the strictly positive occurrence
of $y$ in the matrix is not restricted in antecedent of the matrix ($RV(\neg q(x)) = \emptyset$).

Following (Cabalar et al., 2009), we define the following transformations.

- $\neg \bot \mapsto \top$, $\neg \top \mapsto \bot$
- $\bot \land F \mapsto \bot$, $F \land \bot \mapsto \bot$, $\top \land F \mapsto F$, $F \land \top \mapsto F$
- $\bot \lor F \mapsto F$, $F \lor \bot \mapsto F$, $\top \lor F \mapsto \top$, $F \lor \top \mapsto \top$
- $\bot \rightarrow F \mapsto \top$, $F \rightarrow \top \mapsto \top$, $\top \rightarrow F \mapsto F$

We say that a variable $x$ is positively weakly restricted in a formula $G$ if the
formula obtained from $G$ by

- first replacing every atomic formula $A$ in it such that $x$ is restricted in $A$ by $\bot$,
• and then applying the transformations above

is $T$. Similarly, we say that $x$ is \textit{negatively weakly restricted} in $G$ if the formula obtained from $G$ by the same procedure is $\bot$.

We say that a CPV-semi-safe sentence (6.3) is \textit{CPV-safe} if, for every occurrence of each of the variables $x_i$ in the matrix $M$,

(a) if $Q_i$ is $\forall$, then the occurrence belongs to

- a positive subformula of (6.3) in which $x_i$ is positively weakly restricted,
  or
- a negative subformula of (6.3) in which $x_i$ is negatively weakly restricted;

(b) if $Q_i$ is $\exists$, then the occurrence belongs to

- a negative subformula of (6.3) in which $x_i$ is positively weakly restricted,
  or
- a positive subformula of (6.3) in which $x_i$ is negatively weakly restricted.

It follows that if a sentence is safe according to our definition, it is also CPV-safe. For example, consider the sentence (6.4), which is safe according to our definition. This sentence is CPV-safe because of the following reasons. By replacing $p(x)$ and $r(x)$ by $\bot$, the matrix reduces to $T$ upon applying the transformations shown above. This implies that $x$ is positively weakly restricted in the matrix, which is a positive subformula of (6.4). Also, the variable $y$, which is existentially quantified, is clearly negatively weakly restricted in $q(y)$, which is a positive subformula of (6.4). On the other hand, a CPV-safe sentence may not be safe according to our definition. For example, formula

$$\neg p(x) \rightarrow \neg q(x)$$
is CPV-safe but not safe according to our definition.

One can check that

$$\exists x \forall y ((p(x) \rightarrow q(y)) \rightarrow r)$$

and

$$\exists x (\neg p(x) \rightarrow q)$$

are CPV-safe, but

$$\forall x (\neg p(x) \lor \neg q(x) \rightarrow r)$$

is CPV-semi-safe but not CPV-safe.

6.4 Proofs

Proof of Proposition 3

The notation that we use in the proof involves predicate expressions of the form

$$\lambda x F(x)$$, \quad (6.10)

where \( F(x) \) is a formula. If \( e \) is (6.10) and \( G(p) \) is a formula containing a predicate constant \( p \) of the same arity as the length of \( x \) then \( G(e) \) stands for the result of replacing each atomic part of the form \( p(t) \) in \( G(p) \) with \( F(t) \), after renaming the bound variables in \( G(p) \) in the usual way, if necessary. For instance, if \( G(p) \) is \( p(a) \lor p(b) \) then \( G(\lambda y(x = y)) \) is \( x = a \lor x = b \). Substituting a tuple \( e \) of predicate expressions for a tuple \( p \) of predicate constants is defined in a similar way.

For any finite set \( c \) of object constants, by \( e_c \) we denote the list of predicate expressions

$$\lambda x (p_i(x) \land in_c(x))$$

for all predicate constants \( p_i \).

The following lemma can be proved by induction on \( F \).
Lemma 10  For any quantifier-free formula $F$ and any finite set $c$ of object constants containing $c(F)$,
\[
F^*(e_c) \rightarrow in_c(RV(F))
\]
is logically valid.

About a variable $x$ occurring in a quantifier-free formula $F$ we say that it is safe in $F$ if every occurrence of $x$ in $F$ belongs to a subformula $G \rightarrow H$ such that $x$ is restricted in $G$. It is clear that a sentence in prenex form is semi-safe iff all variables in its matrix are safe. By $NS(F)$ we will denote the set of the variables of $F$ that are not safe.

Lemma 11  For any quantifier-free formula $F$ and any finite set $c$ of object constants containing $c(F)$,
\[
(F \land in_c(NS(F))) \rightarrow F^*(e_c)
\]
is logically valid.

Proof.  By induction on $F$. We only consider the case when $F$ is $G \rightarrow H$; the other cases are straightforward. By the induction hypothesis,
\[
(H \land in_c(NS(H))) \rightarrow H^*(e_c)
\]
is logically valid. By Lemma 1,
\[
G^*(e_c) \rightarrow G
\]
is logically valid. By Lemma 10,
\[
G^*(e_c) \rightarrow in_c(RV(G))
\]
is logically valid. Assume the antecedent of (6.11)
\[
(G \rightarrow H) \land in_c(NS(G \rightarrow H)).
\]
Assume $G^*(e_c)$; our goal is to derive $H^*(e_c)$. By (6.13), $G$; by the first conjunctive term of (6.15), $H$. By (6.14),

$$in_c(RV(G)).$$

(6.16)

Note that $NS(H) \subseteq NS(G \rightarrow H) \cup RV(G)$. Consequently, from the second conjunctive term of (6.15), and (6.16),

$$in_c(NS(H)).$$

(6.17)

From $H$, (6.17) and (6.12), $H^*(e_c)$.

\[\square\]

Lemma 12  For any semi-safe sentence $F$, $F$ entails $F^*(e_c)$.

Proof. Immediate from Lemma 11.

\[\square\]

Proof of Proposition 3  Assume $F$ and $\neg SPP_{c(F)}$; we will derive

$$\exists u(u < p \land F^*(u)).$$

To this end, we will prove

$$(e_{c(F)} < p) \land F^*(e_{c(F)}).$$

By Lemma 12, it is sufficient to prove the first conjunctive term, that is,

$$\bigwedge_{p \in P} \left( \forall x \left( p(x) \land in_{c(F)}(x) \rightarrow p(x) \right) \right)$$

$$\land \neg \bigwedge_{p \in P} \forall x \left( p(x) \rightarrow \left( p(x) \land in_{c(F)}(x) \right) \right).$$

(6.18)

The first conjunctive term of (6.18) is logically valid, and the second is equivalent to $\neg SPP_{c(F)}$.

\[\square\]
Proof of Theorem 17

As in (Lifschitz, Pearce, & Valverde, 2007), by $\text{INT}^=$ we denote intuitionistic predicate logic with equality, and $\text{DE}$ stands for the decidable equality axiom

$$x = y \lor x \neq y.$$  

The importance of the logical system $\text{INT}^= + \text{DE}$ is determined by the fact that it is a part of $\text{SQHT}^=$ ("static quantified logic of here-and-there with equality") (Ferraris et al., 2011), so that the provability of a sentence $F \leftrightarrow G$ in this system implies that $\text{SM}[F]$ is equivalent to $\text{SM}[G]$.

We will first prove the following proposition.

**Proposition 4** For any safe sentence $F$ and any nonempty finite set $c$ of object constants containing $c(F)$, the equivalence

$$\text{Ground}_c[F] \leftrightarrow F$$

is derivable from $\text{SPP}_c$ in $\text{INT}^= + \text{DE}$.

**Lemma 13** If any of the sentences $\forall x F(x)$, $\exists x F(x)$ is safe then so is $F(c)$ for any object constant $c$.

**Proof.** Immediate from the fact, easily verified by induction, that if a variable other than $x$ is restricted in a formula $G(x)$ then it is restricted in $G(c)$ as well. \qed

**Lemma 14** If $x$ is restricted in a quantifier-free formula $F(x)$, and $c$ is a nonempty finite set of object constants containing $c(F)$, then the formula

$$F(x) \rightarrow \text{in}_c(x)$$

is derivable from $\text{SPP}_c$ in $\text{INT}^=$.
Proof. Immediate by induction on $F(x)$. \hfill \Box 

Lemma 15  For any formula $F(x)$ in prenex form that has no free variables other than $x$, and for any nonempty finite set $c$ of object constants containing $c(F)$,

(a) if the sentence $\forall x F(x)$ is safe then the equivalence

$$\forall x F(x) \iff \bigwedge_{c \in c} F(c)$$

is derivable from $SPP_c$ in $INT = +DE$;

(b) if the sentence $\exists x F(x)$ is safe then the equivalence

$$\exists x F(x) \iff \bigvee_{c \in c} F(c)$$

is derivable from $SPP_c$ in $INT = +DE$.

Proof. (a) Assume that $\forall x F(x)$ is safe. In $INT = +DE$, this formula can be equivalently written as

$$\forall x ((in_c(x) \to F(x)) \land (\neg in_c(x) \to F(x))),$$

and consequently as

$$\bigwedge_{c \in c} F(c) \land \forall x (\neg in_c(x) \to F(x)). \tag{6.19}$$

Consider the maximal subformulas $G(x) \to H(x)$ of $F(x)$, positive in $F(x)$, such that $x$ is restricted in $G(x)$. From Lemma 14 we conclude that for each of these subformulas, the implication

$$G(x) \to in_c(x)$$

is derivable from $SPP_c$ in $INT =$, and consequently so is

$$\neg in_c(x) \to (G(x) \to H(x)).$$
It follows that, under the assumption \( SPP_c \), (6.19) can be equivalently rewritten as

\[
\bigwedge_{c \in c} F(c) \land \forall x (\neg in_c(x) \rightarrow S),
\]

where \( S \) is the formula obtained from \( F(x) \) by replacing each of these maximal subformulas \( G(x) \rightarrow H(x) \) with \( \top \). Since \( \forall x F(x) \) is safe, \( x \) does not occur in \( S \). It follows that \( S \) can be obtained from \( F(c) \) in the same way as it was obtained from \( F(x) \), that is, by replacing some subformulas that are positive in \( F(c) \) with \( \top \). Consequently, the formula \( F(c) \rightarrow S \) is intuitionistically provable, and so is

\[
F(c) \rightarrow \forall x (\neg in_c(x) \rightarrow S).
\]

It follows that the second conjunctive term of (6.20) can be dropped.

(b) Assume that \( \exists x F(x) \) is safe. In \( \text{INT}^- + \text{DE} \), this formula can be equivalently written as

\[
\exists x ((in_c(x) \land F(x)) \lor (\neg in_c(x) \land F(x))),
\]

and consequently as

\[
\bigvee_{c \in c} F(c) \lor \exists x (\neg in_c(x) \land F(x)).
\]

Consider the maximal subformulas \( G(x) \rightarrow H(x) \) of \( F(x) \), negative in \( F(x) \), such that \( x \) is restricted in \( G(x) \). As before, the implications

\[
\neg in_c(x) \rightarrow (G(x) \rightarrow H(x))
\]

are derivable from \( SPP_c \) in \( \text{INT}^- \). Consequently, under the assumption \( SPP_c \), (6.21) can be equivalently rewritten as

\[
\bigvee_{c \in c} F(c) \lor \exists x (\neg in_c(x) \land S),
\]

where \( S \) is the formula obtained from \( F(x) \) by replacing each of these subformulas with \( \top \). Since \( \exists x F(x) \) is safe, \( x \) does not occur in \( S \). It follows that \( S \) can be
obtained from \( F(c) \) in the same way as it was obtained from \( F(x) \), that is, by replacing some subformulas that are negative in \( F(c) \) with \( \top \). Consequently, the formula \( S \rightarrow F(c) \) is intuitionistically provable, and so is

\[
\exists x (\neg in_c(x) \land S) \rightarrow F(c).
\]

It follows that the second disjunctive term of (6.22) can be dropped. \( \square \)

**Proof of Proposition 4.** By induction on the length of the prefix. The base case is trivial. Assume that \( QxF(x) \) is safe. Case 1: \( Q \) is \( \forall \). In view of Lemma 13, from the induction hypothesis we can conclude that

\[
\text{Ground}_c[F(c)] \leftrightarrow F(c)
\]

is derivable from \( SPP_c \) in \( \text{INT}^= + \text{DE} \) for every \( c \in \textbf{c} \). Consequently

\[
\bigwedge_{c \in \textbf{c}} \text{Ground}_c[F(c)] \leftrightarrow \bigwedge_{c \in \textbf{c}} F(c)
\]

is derivable from \( SPP_c \) as well. By the definition of \( \text{Ground}_c \), the left-hand side is \( \text{Ground}_c[\forall xF(x)] \). By Lemma 15(a), under the assumption \( SPP_c \), the right-hand side is equivalent in \( \text{INT}^= + \text{DE} \) to \( \forall xF(x) \). Case 2: \( Q \) is \( \exists \). Similar, using Lemma 15(b). \( \square \)

**Proof of Theorem 17.** By Proposition 4 proved above, the equivalence

\[
\text{Ground}_c[F] \land SPP_c \leftrightarrow F \land SPP_c
\]

is provable in \( \text{INT}^= + \text{DE} \). Consequently

\[
\text{SM}[\text{Ground}_c[F] \land SPP_c] \text{ is equivalent to } \text{SM}[F \land SPP_c].
\]

Since \( SPP_c \) is negative on all predicates, it follows from Lemma 4 that

\[
\text{SM}[\text{Ground}_c[F]] \land SPP_c \text{ is equivalent to } \text{SM}[F] \land SPP_c.
\]
In view of Proposition 3 and the fact that \( c(F) \subseteq c \), the conjunctive term \( SM[F] \) in the second conjunction entails its other conjunctive term \( SPP_c \), and the latter can be dropped. Furthermore, \( \text{Ground}_c[F] \) is variable-free and consequently safe. It follows by similar reasoning that in the first conjunction the term \( SPP_c \) can be dropped also.

\[ \text{Proof of Theorem 18} \]

In view of Proposition 3, we need to find a variable-free formula \( G \) such that \( SPP_{c(F)} \) entails \( SM[F] \leftrightarrow G \).

Case 1: \( c(F) = \emptyset \). Under the assumption \( SPP_\emptyset \), every atomic part of \( SM[F] \) that contains a predicate constant or variable of arity \( > 0 \) can be equivalently replaced by \( \bot \). The result is a second-order propositional formula, so that it is equivalent to a propositional formula.

Case 2: \( c(F) \neq \emptyset \) and \( F \) is variable-free. The only quantifiers in the definition of \( SM \) are the second-order quantifiers \( \exists u \). Clearly \( SPP_{c(F)} \) entails

\[ u_i \leq p_i \implies u_i \leq \lambda x \left( \bigvee_c x = c \right) \]

where \( c \) ranges over the tuples of members of \( c(F) \) of the same length as \( x \).

Consequently it entails also

\[ u < p \implies u_i \leq \lambda x \left( \bigvee_c x = c \right) \]

and

\[ u < p \implies \bigvee_C \left( u_i = \lambda x \bigvee_{c \in C} x = c \right), \]

where \( C \) ranges over all sets of such tuples. It follows that under the assumption \( SPP_{c(F)} \) the quantifiers \( \exists u \) can be equivalently replaced by finite disjunctions, with expressions of the form \( \lambda x \bigvee_{c \in C} x = c \) substituted for the variables \( u_i \). The result is a variable-free formula with the required properties.
Case 3: $c(F) \neq \emptyset$ and $F$ is not variable-free. The part of Theorem 18 corresponding to Case 2 can be applied to $\text{Ground}_{c(F)}[F]$. Since the formulas $F$ and $\text{Ground}_{c(F)}[F]$ contain the same object constants, we can assert that, for some variable-free formula $G$, $SPP_{c(F)}$ entails

$$\text{SM}[\text{Ground}_{c(F)}[F]] \leftrightarrow G.$$  

It remains to observe that, by Theorem 17, the left-hand side is equivalent to $\text{SM}[F]$. □

Proof of Theorem 19

From Theorem 18, it follows that there is a variable-free formula $G$ such that $\text{SM}[F]$ is equivalent to $G \land SPP_{c(F)}$. The result follows from the observation that $I \models G \land SPP_{c(F)}$ iff the extension of $I$ to $X$ satisfies $G \land SPP_{c(F)}$. □

Proof of Theorem 20

From Theorem 17, it follows that $\text{SM}[\text{Ground}_{c(F)}[F]]$ is equivalent to $\text{SM}[F]$. The result follows from Proposition 3. □
Chapter 7

EVENT CALCULUS IN ANSWER SET PROGRAMMING

In this chapter, we use the results presented in the previous chapters to reformulate the event calculus in ASP. We begin with a review of the event calculus and then show how the theorem on canonical formulas (Theorem 4) and the splitting theorem (Theorem 12) can be used to reformulate the event calculus in the first-order stable model semantics. We then show how translation F2LP (Chapter 5.3) can be used to further transform event calculus theories into the syntax of ASP. Based on this, we show how system F2LP can be used for computing event calculus descriptions and discuss some of the advantages of this approach. We then compare this computational approach to some existing reasoners, primarily the DEC reasoner1 (Mueller, 2004).

7.1 Review of the Event Calculus

Here we review the syntax of circumscriptive event calculus described in (Mueller, 2006, Chapter 2).

The language of the event calculus is a many-sorted first-order language, which contains an event sort, a fluent sort, and a timepoint sort. A fluent term is a term whose sort is a fluent; an event term and a timepoint term are defined similarly. Some of the key event calculus predicates that are used to represent the knowledge about the occurrences of events and the values of the fluents are as follows:

- \textit{HoldsAt}(f, t): fluent \( f \) is true at timepoint \( t \);
- \textit{Happens}(e, t): event \( e \) occurs at timepoint \( t \);
- \textit{Initiates}(e, f, t): if event \( e \) occurs at timepoint \( t \), then fluent \( f \) is true after \( t \);

1\text{http://decreasoner.sourceforge.net/}.
• **Terminates**(*e, f, t*): if event *e* occurs at timepoint *t*, then fluent *f* is false after *t*;

• **Releases**(*e, f, t*): if event *e* occurs at timepoint *t*, then fluent *f* is released from the commonsense law of inertia after *t*;

• **ReleasedAt**(*f, t*): fluent *f* is released from the commonsense law of inertia at timepoint *t*.

A *condition* is defined recursively as follows:

- If *τ*₁ and *τ*₂ are terms, then comparisons *τ*₁ < *τ*₂, *τ*₁ ≤ *τ*₂, *τ*₁ ≥ *τ*₂, *τ*₁ > *τ*₂, *τ*₁ = *τ*₂, *τ*₁ ≠ *τ*₂ are conditions;

- If *f* is a fluent term and *t* is a timepoint term, then HoldsAt(*f, t*) and ¬HoldsAt(*f, t*) are conditions;

- If *γ*₁ and *γ*₂ are conditions, then *γ*₁ ∧ *γ*₂ and *γ*₁ ∨ *γ*₂ are conditions;

- If *v* is a variable and *γ* is a condition, then ∃*v* γ is a condition.

In the following, we will use *e* and *eᵢ* to denote event terms, *f* and *fᵢ* to denote fluent terms, *t* and *tᵢ* to denote timepoint terms, and *γ* and *γᵢ* to denote conditions.

In the event calculus, **Initiates**, **Terminates**, and **Releases** are circumscribed to minimize unexpected effects of events, **Happens** is circumscribed to minimize unexpected events, and every abnormality predicate **Abᵢ** is circumscribed to minimize abnormalities. Formally, an **event calculus description** is a circumscripтив theory of the form
\[ \text{CIRC}[\Sigma \land \text{Initiates, Terminates, Releases}] \land \text{CIRC}[\Delta \land \text{Happens}] \]

\[ \land \text{CIRC}[\Theta \land \text{Ab}_1, \ldots, \text{Ab}_n] \land \Xi \]

where

- \( \Sigma \) is a conjunction of universal closures of axioms of the form
  \[ \gamma \rightarrow \text{Initiates}(e, f, t) \]
  \[ \gamma \rightarrow \text{Terminates}(e, f, t) \]
  \[ \gamma \rightarrow \text{Releases}(e, f, t) \]
  \[ \gamma \land \pi_1(e, f_1, t) \rightarrow \pi_2(e, f_2, t) \] ("effect constraint")
  \[ \gamma \land [\neg] \text{Happens}(e_1, t) \land \cdots \land [\neg] \text{Happens}(e_n, t) \rightarrow \text{Initiates}(e, f, t) \]
  \[ \gamma \land [\neg] \text{Happens}(e_1, t) \land \cdots \land [\neg] \text{Happens}(e_n, t) \rightarrow \text{Terminates}(e, f, t) \]
  where each of \( \pi_1 \) and \( \pi_2 \) is either \text{Initiates} or \text{Terminates} ('[\neg]' means that '¬' is optional);

- \( \Delta \) is a conjunction of universal closures of temporal ordering formulas
  (comparisons between timepoint terms) and axioms of the form
  \[ \gamma \rightarrow \text{Happens}(e, t) \]
  \[ \sigma(f, t) \land \pi_1(f_1, t) \land \cdots \land \pi_n(f_n, t) \rightarrow \text{Happens}(e, t) \] ("causal constraints")
  \[ \text{Happens}(e, t) \rightarrow \text{Happens}(e_1, t) \lor \cdots \lor \text{Happens}(e_n, t) \] ("disjunctive event axiom")
  where \( \sigma \) is \text{Started} or \text{Stopped} and each \( \pi_j \) \((1 \leq j \leq n)\) is either \text{Initiated} or \text{Terminated};

- \( \Theta \) is a conjunction of universal closures of cancellation axioms of the form
  \[ \gamma \rightarrow \text{Ab}_i(..., t); \]

- \( \Xi \) is a conjunction of first-order sentences (outside the scope of CIRC)
  including unique name axioms, state constraints, action precondition
axioms, event occurrence constraints, trajectory/antitrajectory axioms, observations, and the set of domain-independent axioms in the event calculus, such as EC and DEC axioms (Mueller, 2006). It also includes the following definitions of the predicates used in the causal constraints in $\Delta$:

\[
\text{Started}(f, t) \overset{\text{def}}{\iff} \left( \text{HoldsAt}(f, t) \lor \exists e (\text{Happens}(e, t) \land \text{Initiates}(e, f, t)) \right) \quad (CC_1)
\]

\[
\text{Stopped}(f, t) \overset{\text{def}}{\iff} \left( \neg \text{HoldsAt}(f, t) \lor \exists e (\text{Happens}(e, t) \land \text{Terminates}(e, f, t)) \right) \quad (CC_2)
\]

\[
\text{Initiated}(f, t) \overset{\text{def}}{\iff} \left( \text{Started}(f, t) \land \neg \exists e (\text{Happens}(e, t) \land \text{Terminates}(e, f, t)) \right) \quad (CC_3)
\]

\[
\text{Terminated}(f, t) \overset{\text{def}}{\iff} \left( \text{Stopped}(f, t) \land \neg \exists e (\text{Happens}(e, t) \land \text{Initiates}(e, f, t)) \right) \quad (CC_4).
\]

For example, the “Yale Shooting” (Hanks & McDermott, 1987) scenario can be represented in the event calculus as follows:

\[
\text{Initiates}(\text{Load}, \text{Loaded}, t)
\]

\[
\text{HoldsAt}(\text{Loaded}, t) \rightarrow \text{Terminates}(\text{Shoot}, \text{Alive}, t)
\]

\[
\text{Terminates}(\text{Shoot}, \text{Loaded}, t)
\]

\[
\text{HoldsAt}(\text{Alive}, 0) \land \neg \text{HoldsAt}(\text{Loaded}, 0)
\]

\[
\text{Happens}(\text{Load}, 0) \land \text{Happens}(\text{Wait}, 1) \land \text{Happens}(\text{Shoot}, 2)
\]

In addition to these axioms, there are the unique name axioms and the domain-independent axioms. The domain-independent axioms include inertial axioms, and the axioms that make a fluent true/false based on the occurrence of events that affect it. For example, in the Discrete Event Calculus (DEC), the following axioms make a fluent true/false based on the occurrence of events that
affect it:

\[ \text{Happens}(e, t) \land \text{Initiates}(e, f, t) \rightarrow \text{HoldsAt}(f, t + 1) \]
\[ \text{Happens}(e, t) \land \text{Terminates}(e, f, t) \rightarrow \neg \text{HoldsAt}(f, t + 1). \]

The following \textit{DEC} axioms ensure that the value of a fluent does not change unless some event that affects it occurs or unless it is released from the commonsense law of inertia:

\[ \text{HoldsAt}(f, t) \land \neg \text{ReleasedAt}(f, t + 1) \land \neg \exists e (\text{Happens}(e, t) \land \text{Terminates}(e, f, t)) \rightarrow \text{HoldsAt}(f, t + 1) \]
\[ \neg \text{HoldsAt}(f, t) \land \neg \text{ReleasedAt}(f, t + 1) \land \neg \exists e (\text{Happens}(e, t) \land \text{Initiates}(e, f, t)) \rightarrow \neg \text{HoldsAt}(f, t + 1). \]

In the “Yale Shooting” scenario, since \textit{Happens} is minimized, the only events that occur are those that are specified by the event occurrence formula (the last formula), and since \textit{Initiates} and \textit{Terminates} are minimized, no unexpected effects of events occur. As a result, the gun remains loaded after the \textit{Wait} action occurs since the action does not affect any fluent.

7.2 Reformulating the Event Calculus in the First-Order Stable Model Semantics

We assume that \( \Xi \) in (7.1) was already equivalently rewritten so that it is negative on \( \{\text{Initiates, Terminates, Releases, Happens, } Ab_1, \ldots, Ab_n\} \).

The following facts are easy to check from the description of the event calculus (7.1), and the definition of canonical formulas (Chapter 3.3):

- \( \Sigma \) is canonical relative to \( \{\text{Initiates, Terminates, Releases}\} \);
- \( \Delta \) is canonical relative to \( \{\text{Happens}\} \);
- \( \Theta \) is canonical relative to \( \{\text{Ab}_1, \ldots, \text{Ab}_n\} \).

\(^2\)Recall the definition of a \textit{negative formula on} \( p \) given in Chapter 4.
These facts enable us to reformulate the event calculus in the first-order stable model semantics. The following theorem shows a few equivalent reformulations of circumscriptive event calculus in the first-order stable model semantics.

**Theorem 21** For any event calculus description (7.1), the following theories are equivalent to each other:³

(a) \( \text{CIRC}[\Sigma; I, T, R] \land \text{CIRC}[\Delta; H] \land \text{CIRC}[\Theta; Ab_1, \ldots, Ab_n] \land \Xi \);  

(b) \( \text{SM}[\Sigma; I, T, R] \land \text{SM}[\Delta; H] \land \text{SM}[\Theta; Ab_1, \ldots, Ab_n] \land \Xi \);  

(c) \( \text{SM}[\Sigma \land \Delta \land \Theta \land \Xi; I, T, R, H, Ab_1, \ldots, Ab_n] \);  

(d) \( \text{SM}[\Sigma \land \Delta \land \Theta \land \Xi \land \text{Choice}(pr(\Sigma \land \Delta \land \Theta \land \Xi) \setminus \{I, T, R, H, Ab_1, \ldots, Ab_n\})] \).

The equivalence between (a) and (b) is immediate from the theorem on canonical formulas (Theorem 4). The equivalence between (b) and (c) can be proved using the splitting theorem (Chapter 4.1). The assumption that \( \Xi \) is negative on the intensional predicates is essential in showing this equivalence. (For more details, see the proof in the Appendix.) The equivalence between (c) and (d) follows from Proposition 1 since 
\[ \{I, T, R, H, Ab_1, \ldots, Ab_n\} \setminus \text{pr}(\Sigma \land \Delta \land \Theta \land \Xi) \] is the empty set.⁴

7.3 Reformulating the Event Calculus in Answer Set Programming

Using translation F2LP (Chapter 5.3), we can further turn the event calculus reformulation shown above (Chapter 7.2) into answer set programs.

The following procedure turns an event calculus description into an answer set program.

³For brevity, we abbreviate the names of circumscribed predicates.
⁴\( I, T, R, H \) occur in the domain independent axioms as part of \( \Xi \).
Definition 3 (Translation EC2ASP) 1. Given an event calculus description (7.1), rewrite all the definitional axioms of the form

$$\forall x(p(x) \overset{\text{def}}{\iff} G)$$

in $\Xi$ as $\forall x(G \neg\neg \rightarrow p(x))$ where $G\neg\neg$ is obtained from $G$ by prepending $\neg\neg$ to all occurrences of the intensional predicates Initiates, Terminates, Releases, Happens, $Ab_1, \ldots, Ab_n$. Also prepend $\neg\neg$ to the strictly positive occurrences of the intensional predicates in the remaining axioms of $\Xi$. Let $\Xi'$ be the resulting formula obtained from $\Xi$.

2. Apply translation F2LP on $\Sigma \land \Delta \land \Theta \land \Xi'$ with intensional predicates

$$\{\text{Initiates, Terminates, Releases, Happens, } Ab_1, \ldots, Ab_n\} \cup p$$

where $p$ is the set of all predicate constants $p$ of (7.2) considered in Step 1.

The following theorem states the correctness of the translation.

Theorem 22 Let $T$ be an event calculus description (7.1) of signature $\sigma$ that contains finitely many predicate constants, let $F$ be the FOL-representation of the program obtained from $T$ by applying translation EC2ASP. Then $T$ is $\sigma$-equivalent to $SM[F]$.

In view of the theorem, system F2LP can be used to compute event calculus descriptions by a simple rewriting as stated in translation EC2ASP.\footnote{In (Kim et al., 2009), we presented a prototype of system F2LP called ECASP that is tailored to the event calculus computation.}

Figure 7.1 shows an F2LP encoding of the domain-independent axioms in the Discrete Event Calculus (DEC) (Mueller, 2006). The file is also available at http://reasoning.eas.asu.edu/f2lp, along with the F2LP encodings of the domain.
independent axioms in other versions of the event calculus. Figure 7.2 shows an F2LP encoding of a simple blocks world domain. In this blocks world encoding, there are only 2 actions: $\text{PickUp}(x,y)$ and $\text{Stack}(x,y)$. $\text{PickUp}(x,y)$ represents the action of picking up block $x$ from the table ($y$) or from the top of another block $y$. $\text{Stack}(x,y)$ represents the action of placing block $x$ on top of another block $y$ or on the table ($y$). Initially, block $a$ is on the table, $c$ is on $a$, and $b$ is on $c$. The goal is to stack the blocks such that $c$ is on the table, $b$ is on $c$, and $a$ is on $b$. The plan can be computed by invoking F2LP along with GRINGO and CLASP-D as follows:

```
$ f2lp dec blocksWorld | gringo -c maxstep=8 | claspD
```

where 8 is the length of the plan. This gives the following plan:

- $\text{happens(pickUp(b),0)}$
- $\text{happens(stack(b,table),1)}$
- $\text{happens(pickUp(c),2)}$
- $\text{happens(stack(c,table),3)}$
- $\text{happens(pickUp(b),4)}$
- $\text{happens(stack(b,c),5)}$
- $\text{happens(pickUp(a),6)}$
- $\text{happens(stack(a,b),7)}$

Figure 7.2: Blocks World in F2LP
7.4 Enhancing Event Calculus Descriptions with Answer Set Programming Rules

As mentioned in the introduction, one of the advantages of ASP-based event calculus reasoning is that we can enhance event calculus descriptions with expressive ASP rules such as the transitive closure rules. We illustrate this using the example from (Doğandağ, Ferraris, & Lifschitz, 2004). There are 9 rooms numbered 1–9 (horizontal, then vertical) and 12 doors as shown in Figure 7.3. Initially the robot “Robby” is in the middle room and all the doors are closed. The goal of the robot is to make all rooms accessible from each other. Figure 7.4 (File ‘robby’) shows an encoding of the problem in the language of F2LP. Atom door(x, y) denotes that there is a door between rooms x and y; open(x, y) denotes the event “Robby opening the door between rooms x and y”; goto(x) denotes the event “Robby going to room x”; opened(x, y) denotes that the door between x and y has been opened; inRoom(x) denotes that Robby is in room x; accessible(x, y) denotes that y is accessible from x. Note that the rules defining the relation accessible are not part of event calculus axioms (Chapter 7.1). This example illustrates an advantage of allowing ASP rules in event calculus descriptions.

The minimal number of steps to solve the given problem is 11. We can find such a plan using the combination of F2LP, GRINGO and CLASP in the following way:
% File 'robby'

% objects
step(0..maxstep).
astep(0..maxstep-1).
room(1..9).

% variables
#domain step(T).
#domain room(R).
#domain room(R1).
#domain room(R2).

% position of the doors
R1 >= 1 & R2 >=1 & R1 < 4 & R2 < 4 & R2 = R1+1 -> door(R1,R2).
R1 >= 4 & R2 >= 4 & R1 < 7 & R2 < 7 & R2 = R1+1 -> door(R1,R2).
R1 >= 7 & R2 >= 7 & R1 < 10 & R2 < 10 & R2 = R1+1 -> door(R1,R2).
R2 < 10 & R2 = R1+3 -> door(R1,R2).

door(R2,R1) -> door(R1,R2).

% fluents
door(R1,R2) -> fluent(opened(R1,R2)).
fluent(inRoom(R)).
% F ranges over the fluents
#domain fluent(F).

% events
door(R1,R2) -> event(open(R1,R2)).
event(goto(R)).
% E and E1 range over the events
#domain event(E).
#domain event(E1).

% effect axioms
initiates(open(R,R1),opened(R,R1),T).
initiates(open(R,R1),opened(R1,R),T).

holdsAt(opened(R1,R2),T) & holdsAt(inRoom(R1),T) -> initiates(goto(R2),inRoom(R2),T).

holdsAt(inRoom(R1),T) & initiates(E,inRoom(R2),T) -> terminates(E,inRoom(R1),T).

% action precondition axioms
happens(open(R1,R2),T) -> holdsAt(inRoom(R1),T).
% event occurrence constraint
happens(E,T) & E != E1 -> -happens(E1,T).

% state constraint
holdsAt(inRoom(R1),T) & R1 != R2 -> -holdsAt(inRoom(R2),T).

% accessibility
holdsAt(opened(R,R1),T) -> accessible(R,R1,T).
accessible(R,R1,T) & accessible(R1,R2,T) -> accessible(R,R2,T).

% initial state
-holdsAt(opened(R1,R2),0).
holdsAt(inRoom(5),0).

% goal state
--accessible(R,R1,maxstep).

% happens is exempt from minimization in order to find a plan.
T < maxstep -> {happens(E,T)}.

% all fluents are inertial
-releasedAt(F,0).

Figure 7.4: Robby's apartment in F2LP

$ f2lp dec robby | gringo -c maxstep=11 | claspD

Following is one of the plans found:

happens(open(5,8),0) happens(open(5,2),1) happens(open(5,6),2)
happens(open(5,4),3) happens(goto(4),4) happens(open(4,7),5)
happens(open(4,1),6) happens(goto(5),7) happens(goto(6),8)
happens(open(6,3),9) happens(open(6,9),10)

7.5 Comparison with Other Event Calculus Reasoners

Shanahan (2000) introduced an event calculus planner that uses abductive logic programming to solve abduction and planning problems.\(^6\) Later, Shanahan and Witkowski (2004) introduced a SAT-based event calculus planner that showed significant improvements over the abductive planner. Based on the reduction of

\(^6\)http://www.iis.ee.ic.ac.uk/~mpsha/planners.html
circumscription to completion (Chapter 3.1, Theorems 1 and 2), Mueller (2004) introduced a SAT-based event calculus reasoner that not only solves abduction and planning problems but also solves other interesting problems such as projection and postdiction. This system is called the DEC reasoner. While the system handles a large fragment of the event calculus, it still cannot handle recursive and disjunctive axioms, such as effect constraints and disjunctive event axioms (Chapter 7.1), since completion cannot be applied to descriptions containing such axioms. For example, the DEC reasoner does not allow the following effect constraints which describe the indirect effects of an agent’s walking on the objects that he is holding:

\[
\text{HoldsAt} (\text{Holding}(a, o), t) \land \text{Initiates}(e, \text{InRoom}(a, r), t) \\
\quad \rightarrow \text{Initiates}(e, \text{InRoom}(o, r), t)
\]

\[
\text{HoldsAt} (\text{Holding}(a, o), t) \land \text{Terminates}(e, \text{InRoom}(a, r), t) \\
\quad \rightarrow \text{Terminates}(e, \text{InRoom}(o, r), t).
\] (7.3)

Our ASP-based approach on the other hand can handle the full version of the event calculus under the assumption that the domain is given and finite.

We compared the performance of the DEC reasoner (v 1.0) running MINISAT (v 2.2) with the following:

- F2LP (v 1.11) with LPARSE (v 1.0.17)+CMODELS (v 3.79) running MINISAT (v 2.0 beta),

- F2LP (v 1.11) with GRINGO (v 3.0.3)+CMODELS (v 3.79) running MINISAT (v 2.0 beta),

- F2LP (v 1.11) with GRINGO (v 3.0.3) +CLASP (v 2.0.2) (CLASP(D) (v 1.1.2) used instead for disjunctive programs), and

---

8Similar results were observed when RELSAT (v 2.2) was used with the DEC reasoner.
F2LP (v 1.11) with CLINGO (v 3.0.3 (CLASP v 1.3.5)).

F2LP turns an input theory into the languages of LPARSE and GRINGO, and LPARSE and GRINGO turn the result into a ground ASP program. CMODELS turns this ground program into a set of clauses and then invokes a SAT solver to compute answer sets, while CLASP computes answer sets using the techniques similar to those used in SAT solvers but without actually invoking them. CLINGO is a system that combines GRINGO and CLASP in a monolithic way.

</tbody>
</table>
The first five examples in Figure 7.5 are part of the benchmark problems from the work of Shanahan (1997, 1999). The next four are by Mueller (2006). (We increased timepoints to see more notable differences.) More examples can be found from the F2LP homepage. All experiments were done on a Pentium machine with 3.06 GHz CPU and 4GB RAM running 64 bit Linux. The reported run times are in seconds and were obtained using the Linux `time` command ("user time + sys time"), except for the DEC reasoner for which we recorded the times reported by the system. This was to avoid including the time spent by the DEC reasoner in producing output in a neat format, which sometimes takes non-negligible time. For the DEC reasoner, the times in parentheses are "(encoding time + SAT solving time)." For the others, they are the times spent by each of the grounder and the solver. CMODELS time includes the time spent in converting the ground program generated by LPARSE/GRINGO into a set of clauses, and calling the SAT solver. The time spent by F2LP in translating an event calculus description into an answer set program (with variables) is negligible for these problems.

The symbol ‘—’ denotes that the system cannot solve the problem due to the limited expressivity. For instance, BusRide includes disjunctive event axioms, which results in a disjunctive program that cannot be handled by CLINGO. Similarly, the DEC reasoner cannot handle BusRide (disjunctive event axioms), Commuter (compound events) and Walking Turkey (effect constraints). As is evident from the experiments, the main reason for the better performance of the ASP-based approach is the efficient grounding mechanisms implemented in the ASP grounders. Though the DEC reasoner and CMODELS call the same SAT solver MINISAT, the number of atoms produced by the DEC reasoner is in general much smaller. This is because the DEC reasoner adopts an optimized encoding method (that is based on predicate completion) which avoids a large number of ground instances of atoms such as Initiates(e, f, t), Terminates(e, f, t), and

A: number of atoms, C: number of clauses, R: number of ground rules

Figure 7.6: Zoo World in DEC reasoner vs. Zoo World in F2LP + answer set solvers

Releases (e, f, t) (Mueller, 2004, Section 4.4). On the other hand, in several examples, the number of clauses generated by CMODELS is 0, which means that the answer sets were found without calling the SAT solver. This is because for these examples the unique answer set coincides with the well-founded model, which is efficiently computed by CMODELS in a preprocessing step before calling SAT solvers. Out of the 14 benchmark examples by Shanahan (1997, 1999), 10 of them belong to this case when LPARSE is used for grounding.

In the experiments in Figure 7.5, the solving times are negligible for most of the problems. We also experimented with some computationally hard problems, where solving takes more time than grounding. Figure 7.6 shows runs of a medium-size action domain, the Zoo World (Akman, Erdoğan, Lee, Lifschitz, & Turner, 2004). All the tests shown in the table are planning problems where “max.step” is the length of a minimal plan. The cut-off time was 2 hours and the DEC reasoner did not terminate within that time for any of the problems. In fact, the entire time was spent on encoding and the SAT solver was never called. On the other hand, the ASP grounder GRINGO took only a few seconds to ground the domain and, unlike in Figure 7.5, the solvers took much more time than the
grounder. As we can see, CMODELS with MINISAT performed better than CLASP on two of the problems. To check the time taken by MINISAT on the encoding generated by the DEC reasoner, we ran ZooTest1 to completion. The DEC reasoner terminated after 116578.1 seconds (32.38 hours) and the time taken by MINISAT (solving time) was just 2 seconds.

7.6 Proofs

Proof of Theorem 21

Between (a) and (b): Follows immediately from Theorem 4.

Between (b) and (c): Note first that $\Xi$ is equivalent to $SM[\Xi; \emptyset]$. Since

- every strongly connected component in the dependency graph (Chapter 3.2) of $\Sigma \land \Delta$ relative to $\{I,T,R,H\}$ either belongs to $\{I,T\}$ or $\{H\}$,
- $\Sigma$ is negative on $\{H\}$, and
- $\Delta$ is negative on $\{I,T,R\}$,

it follows from Theorem 12 that (b) is equivalent to

$$SM[\Sigma \land \Delta; I,T,R,H] \land SM[\Theta; Ab_1, \ldots, Ab_n] \land SM[\Xi; \emptyset]$$

Similarly, applying Theorem 12 repeatedly, we can show that the above formula is equivalent to (c).

Between (c) and (d): By Proposition 1.

Proof of Theorem 22

Assume that $T$ is

$$CIRC[\Sigma; Initiates, Terminates, Releases] \land CIRC[\Delta; Happens]$$

$$\land CIRC[\Theta; Ab_1, \ldots, Ab_n] \land \Xi,$$
which is equivalent to
\[
SM[\Sigma; \text{Initiates, Terminates, Releases}] \land SM[\Delta; \text{Happens}]
\land SM[\Theta; Ab_1, \ldots, Ab_n] \land \Xi
\]  
(7.4)

by Theorem 21.

Let \( \Xi_{def} \) be the set of all definitions (7.2) in \( \Xi \), and let \( \Xi' \) be the formula obtained from \( \Xi \) by applying Step 1. By Theorem 3, it follows that each formula \( (7.2) \) in \( \Xi_{def} \) is equivalent to
\[
SM[\forall x (G' \rightarrow p(x)); p]
\]
where \( G' \) is as described in Step 1. Consequently, (7.4) is equivalent to
\[
SM[\Sigma; \text{Initiates, Terminates, Releases}] \land SM[\Delta; \text{Happens}]
\land SM[\Theta; Ab_1, \ldots, Ab_n] \land \bigwedge_{(7.2) \in \Xi_{def}} SM[\forall x (G' \rightarrow p(x)); p] \land \Xi''
\]  
(7.5)

where \( \Xi'' \) is the conjunction of all the axioms in \( \Xi' \) other than the ones obtained from definitional axioms (7.2).

Applying Theorem 12 repeatedly, it follows that (7.5) is equivalent to
\[
SM[\Sigma \land \Delta \land \Theta \land \Xi'' \land \bigwedge_{(7.2) \in \Xi_{def}} \forall x (G' \rightarrow p(x))];
\]
\( \text{Initiates, Terminates, Releases, Happens, Ab}_1, \ldots, Ab_n, p \) .  
(7.6)

According to the syntax of the event calculus reviewed in Section 7.1,

- every positive occurrence of a formula of the form \( \exists y G(y) \) in (7.6) is contained in a subformula that is negative on

\( \{ \text{Initiates, Terminates, Releases, Happens, Ab}_1, \ldots, Ab_n, p \} \), and

- there are no negative occurrences of any formula of the form \( \forall y G(y) \) in (7.6).

Consequently, the statement of the theorem follows from Theorem 16. \[ \square \]
In this chapter, we use the results from Chapters 3-5 to reformulate Lin’s causal theories (Lin, 1995) and Basic Action Theories (BATs) (Reiter, 2001) in the first-order stable model semantics and in ASP. Based on the reformulations, we show how F2LP can be used to compute these theories, and discuss some of the advantages of this approach.

8.1 Lin’s Causal Theories in Answer Set Programming

In this section, we show how Lin’s causal theories can be reformulated in the first-order stable model semantics and in ASP. We also show how system F2LP can be used to compute these theories.

**Review of Lin’s Causal Theories**

We assume a many-sorted first-order language which contains a *situation* sort, an *action* sort, a *fluent* sort, a *truth value* sort and an *object* sort. We do not consider functional fluents here for simplicity. Expression \( \text{Holds}(P(x), s) \) represents that fluent \( P(x) \) is true in situation \( s \), \( \text{Poss}(a, s) \) represents that action \( a \) can be executed in situation \( s \), and \( \text{Caused}(f, v, s) \) represents that \( f \) is caused to have value \( v \) in situation \( s \) where \( v \in \{\text{true}, \text{false}\} \).

According to Lin (1995), a formula \( \phi(s) \) is called a *simple state formula about* \( s \) if \( \phi(s) \) does not mention \( \text{Poss}, \text{Caused} \) or any situation term other than possibly the variable \( s \).

We assume that a causal action theory \( \mathcal{D} \) consists of a finite number of the following sets of axioms. We often identify \( \mathcal{D} \) with the conjunction of the universal closures of all axioms in \( \mathcal{D} \). In the following, \( F, F_i \) are fluent names, \( A \) is an action name, \( V, V_i \) are truth values, \( s, s’ \) are situation variables, \( \phi(s) \) is a simple state formula about \( s \), symbols \( a, a’ \) are action variables, \( f \) is a variable of sort fluent, \( v \)
is a variable of sort truth value, and $x, x_i, y, y_i$ are lists of variables.

- $\mathcal{D}_{caused}$ is a conjunction of axioms of the form

$$\text{Poss}(A(x), s) \rightarrow (\phi(s) \rightarrow \text{Caused}(F(y), V, do(A(x), s))),$$

(direct effect) and

$$\phi(s) \land \text{Caused}(F_1(x_1), V_1, s) \land \cdots \land \text{Caused}(F_n(x_n), V_n, s) \rightarrow \text{Caused}(F(x), V, s)$$

(indirect effect).

- $\mathcal{D}_{poss}$ is a conjunction of precondition axioms of the form

$$\text{Poss}(A(x), s) \leftrightarrow \phi(s). \quad (8.1)$$

- $\mathcal{D}_{rest}$ is a conjunction of the following axioms:

  - The basic axioms:

    $$\text{Caused}(f, true, s) \rightarrow \text{Holds}(f, s),$$
    $$\text{Caused}(f, false, s) \rightarrow \neg\text{Holds}(f, s),$$
    $$true \neq false \land \forall v = true \lor v = false. \quad (8.2)$$

  - The unique name assumptions for fluent names:

    $$F_i(x) \neq F_j(y), \quad (i \neq j)$$
    $$F_i(x) = F_i(y) \rightarrow x = y. \quad (8.3)$$

    Similarly for action names.

  - The foundational axioms for the discrete situation calculus: $^1$

    $$s \neq do(a, s), \quad (8.4)$$
    $$do(a, s) = do(a', s') \rightarrow (a = a' \land s = s'), \quad (8.5)$$
    $$\forall p\left( p(S_0) \land \forall a, s (p(s) \rightarrow p(do(a, s))) \rightarrow \forall s p(s) \right). \quad (8.6)$$

$^1$For simplicity we omit the two axioms regarding the partial-order among situations.
– The frame axiom:

\[ \text{Poss}(a, s) \rightarrow (\neg \exists v \text{Caused}(f, v, do(a, s))) \]
\[ \rightarrow (\text{Holds}(f, do(a, s)) \leftrightarrow \text{Holds}(f, s))). \]

– Axioms for other domain knowledge: \( \phi(s) \).

A causal action theory is defined as

\[
\text{CIRC}[\mathcal{D}_{\text{caused}}; \text{Caused}] \land \mathcal{D}_{\text{poss}} \land \mathcal{D}_{\text{rest}}.
\] (8.7)

For example, consider the Lin’s suitcase example (Lin, 1995), wherein there is a suitcase with two locks \(L_1, L_2\) and a spring loaded mechanism that opens the suitcase when both the locks are in the \(Up\) position. This can be represented as follows:

\[ \text{Poss}(\text{Flip}(x), s) \rightarrow (\text{Holds}(\text{Up}(x), s) \rightarrow \text{Caused}(\text{Up}(x), \text{false}, \text{do}(\text{Flip}(x), s))) \]
\[ \text{Poss}(\text{Flip}(x), s) \rightarrow (\neg \text{Holds}(\text{Up}(x), s) \rightarrow \text{Caused}(\text{Up}(x), \text{true}, \text{do}(\text{Flip}(x), s))) \]
\[ \text{Holds}(\text{Up}(L_1), s) \land \text{Holds}(\text{Up}(L_2), s) \rightarrow \text{Caused}(\text{Open}, \text{true}, s) \]
\[ \top \leftrightarrow \text{Poss}(\text{Flip}(x), s) \]

The first two axioms represent the direct effects of the action \(\text{Flip}\), and the third axiom is the indirect effect axiom representing that \(\text{Open}\) is caused to be true when both the locks are in the \(Up\) position. Finally, the last axiom represents that the \(\text{Flip}\) action can be executed in every situation.

Reformulating Lin’s Causal Theories in the First-Order Stable Model Semantics

It is easy to check from the description above that \(\mathcal{D}_{\text{caused}}\) is canonical relative to \(\text{Caused}\) (see Chapter 3.3 for definition of canonical relative to \(p\)). This fact enables us to reformulate causal action theories in the first-order stable model semantics.

Let \(\mathcal{D}_{\text{poss}}\) be the conjunction of axioms

\[ \phi(s) \rightarrow \text{Poss}(A(x), s) \]
for each axiom (8.1) in $D_{\text{poss}}$. Instead of the second-order axiom (8.6) we consider the following first-order formula $D_{\text{sit}}$, which introduces a new intensional predicate constant $\text{Sit}$.\footnote{Suggested by Vladimir Lifschitz (personal communication).}

$$\text{Sit}(S_0) \land \forall a, s(\text{Sit}(s) \rightarrow \text{Sit}(\text{do}(a, s))) \land \neg \exists s \neg \text{Sit}(s). \quad (8.8)$$

In the following, $D_{\text{rest}}^{-}$ is the theory obtained from $D_{\text{rest}}$ by dropping (8.6).

**Theorem 23** Given a causal action theory (8.7), the following theories are equivalent to each other when we disregard the auxiliary predicate $\text{Sit}$:

(a) $CIRC[D_{\text{caused}}; \text{Caused}] \land D_{\text{poss}} \land D_{\text{rest}}$;

(b) $SM[D_{\text{caused}}; \text{Caused}] \land D_{\text{poss}} \land D_{\text{rest}}^{-} \land SM[D_{\text{sit}}; \text{Sit}]$;

(c) $SM[D_{\text{caused}}; \text{Caused}] \land SM[D_{\text{poss}^{-}}; \text{Poss}] \land D_{\text{rest}}^{-} \land SM[D_{\text{sit}}; \text{Sit}]$;

(d) $SM[D_{\text{caused}} \land D_{\text{poss}^{-}} \land D_{\text{rest}}^{-} \land D_{\text{sit}}; \text{Caused, Poss, Sit}]$.

The proof of the equivalence between (a) and (b) uses the theorem on canonical formulas (Theorem 4, Chapter 3.3). The equivalence between (b) and (c) follows from the theorem on completion (Ferraris et al., 2011), and the equivalence between (c) and (d) follows from the splitting theorem (Theorem 12, Chapter 4.1). A complete proof is given in the Appendix.

**Reformulating Lin’s Causal Theories in Answer Set Programming**

Using translation F2LP, we can further turn the reformulation of Lin’s causal theories shown above into the syntax of answer set programs.

**Theorem 24** Let $D$ be a finite causal action theory (8.7) of signature $\sigma$ that contains finitely many predicate constants, and let $F$ be the FOL-representation of
the program obtained by applying translation $F2LP$ on

$$D_{\text{caused}} \land D_{\text{poss}} \land D_{\text{rest}} \land D_{\text{sit}}$$  \hspace{1cm} (8.9)

with intensional predicates \{\text{Caused, Poss, Sit}\}. Then $D$ is $\sigma$-equivalent to $SM[F]$.

In view of this theorem, system $F2LP$ can be used to compute Lin’s causal theories. The input to $F2LP$ can be simplified if we are interested in Herbrand stable models (answer sets) only. We can drop axioms (8.2)–(8.5) as they are ensured by Herbrand models. Also, in order to ensure finite grounding, instead of $D_{\text{sit}}$, we include the following set of rules $\Pi_{\text{situation}}$ in the input to $F2LP$.

\begin{align*}
\text{nesting}(0, s0).
\text{nesting}(L, S) & \land L < \text{maxdepth} \rightarrow \text{nesting}(L+1, \text{do}(A, S)). \\
\text{nesting}(L, S) & \rightarrow \text{situation}(S).
\end{align*}

$\Pi_{\text{situation}}$ is used to generate finitely many situation terms whose height is up to $\text{maxdepth}$, the value that can be given as an option in invoking GRINGO. Using the splitting theorem (Theorem 12, Chapter 4.1), it is not difficult to check that if a program $\Pi$ containing the ASP-rules corresponding to $\Pi_{\text{situation}}$ has no occurrence of predicate $\text{nesting}$ in any other rules and has no occurrence of predicate $\text{situation}$ in the head of any other rules, then every answer set of $\Pi$ contains atoms $\text{situation}(\text{do}(a_m, \text{do}(a_{m-1}, \text{do}(\ldots, \text{do}(a_1, s0))))\ldots)$ for all possible sequences of actions $a_1, \ldots, a_m$ for $m=0, \ldots, \text{maxdepth}$. Though the ASP-representation of $\Pi_{\text{situation}}$ does not satisfy syntactic conditions, such as the ones corresponding to $\lambda$-restricted (Gebser, Schaub, & Thiele, 2007), $\omega$-restricted (Syrjänen, 2004), or finite domain programs (Calimeri, Cozza, Ianni, & Leone, 2008), that answer set solvers usually impose in order to ensure finite grounding, the rules can still be finitely grounded by GRINGO Version 3.x, which
does not check such syntactic conditions. It is not difficult to see why the
ASP-rules corresponding to $\Pi_{situation}$ lead to finite grounding since we provide an
explicit upper limit for the nesting depth of function do.

In addition to $\Pi_{situation}$, we use the following rules $\Pi_{executable}$ in order to
represent the set of executable situations (Reiter, 2001):

$$\text{executable(s0).}$$
$$\text{executable(S) & poss(A,S) & -final(S) &}$$
$$\quad \text{situation(S) & action(A) -> executable(do(A,S)).}$$

Figure 8.1 shows an encoding of Lin’s suitcase example (1995) in the
language of F2LP (h is used to represent Holds), which describes a suitcase that
has two locks and a spring loaded mechanism which will open the suitcase when
both locks are up. This example illustrates how the ramification is handled in
causal action theories. Since we fix the domain of situations to be finite, we require
that actions not be effective in the final situations. This is done by introducing atom
final(S).

Consider the simple temporal projection problem by Lin (1995). Initially the
first lock is down and the second lock is up. What will happen if the first lock is
flipped? Intuitively, we expect both locks to be up and the suitcase to be open. We
can verify this by using the combination of F2LP, GRINGO and CLASP-D. First, we
add $\Pi_{executable}$ and the following formulas to the theory in Figure 8.1. In order to
check if the theory entails that flipping the first lock is executable, and that the
suitcase is open after the flipping, we encode the negation of these facts in the last
formula.

```%
% initial situation
-h(up(l1),s0).
```
% File 'suitcase'

% domain and domain variable declarations
lock(l1). lock(l2).
#domain lock(X).

fluent(up(X)). fluent(open).
action(flip(X)).
value(t). value(f).

#domain fluent(F).
#domain action(A).
#domain value(V).

% computing domain of situation
nesting(0,s0).
nesting(L,S) & L < maxdepth -> nesting(L+1,do(A,S)).
nesting(L,S) -> situation(S).
nesting(maxdepth,S) -> final(S).

% basic axioms
situation(S) & caused(F,t,S) -> h(F,S).
situation(S) & caused(F,f,S) -> ~h(F,S).

% effect axioms (D_caused)
situation(S) & ~final(S) & poss(flip(X),S) ->
  (h(up(X),S) -> caused(up(X),f,do(flip(X),S))).
situation(S) & ~final(S) & poss(flip(X),S) ->
  (~h(up(X),S) -> caused(up(X),t,do(flip(X),S))).

% indirect effects
situation(S) & h(up(l1),S) & h(up(l2),S) -> caused(open,t,S).

% pre-conditions (D_poss)
situation(S) -> poss(flip(X),S).

% frame axioms
situation(S) & ~final(S) & poss(A,S) ->
  (? V:caused(F,V,do(A,S)) ->
   (h(F,do(A,S)) <-> h(F,S))).

% Holds is non-intensional
situation(S) -> {h(F,S)}.

Figure 8.1: Lin's Suitcase example in F2LP
h(up(l2),s0).

%! query

- (executable(do(flip(l1),s0)) & h(open,do(flip(l1),s0))).

We check the answer to the temporal projection problem by running the command:

$ f2lp suitcase | gringo -c maxdepth=1 | claspD

CLASP D returns no answer set as expected.

Now, consider a simple planning problem for opening the suitcase when the locks are initially down. We add $\Pi_{\text{executable}}$ and the following rules to the theory in Figure 8.1. The last rule encodes the goal.

%! initial situation

- h(up(l1),s0).
- h(up(l2),s0).
- h(open,s0).

%! goal

--( ?[S]: (executable(S) & h(open,S)) ) .

When maxdepth is 1, the combined use of F2LP, GRINGO and CLASP D results in no answer sets, and when maxdepth is 2, it finds the unique answer set that contains both $h(open,do(flip(l2),do(flip(l1),s0)))$ and $h(open,do(flip(l1),do(flip(l2),s0)))$, each of which encodes a plan. In other words, the single answer set encodes multiple plans in different branches of the situation tree, which allows us to combine information about the different branches in one model. This is an instance of hypothetical reasoning that is elegantly handled in the situation calculus due to its branching time structure.
Bellegem, Denecker, and Schreye (1997) note that the linear time structure of the event calculus is limited to handle such hypothetical reasoning allowed in the situation calculus.

8.2 Basic Action Theories in Answer Set Programming

In this section, we show how BATs can be reformulated in the first-order stable model semantics and in ASP. We also show how system F2LP can be used to compute these theories.

Review of Basic Action Theories

We understand $P(x, s)$ where $P$ is a fluent name, as shorthand for $\text{Holds}(P(x), s)$, and do not consider functional fluents.

According to (Reiter, 2001), a formula is uniform in a situation term $\sigma$ if it satisfies the following conditions:

- it does not contain any quantification over situations;
- it does not mention any variables for relational fluents;
- it does not mention any situation term other than $\sigma$;
- it does not mention any predicate that has a situation argument other than $\text{Holds}$;
- it does not mention any function constant that has a situation argument unless the function is a functional fluent.

Since we do not consider functional fluents, the last item above simply means that functions in uniform formulas do not have any situation argument.

A basic action theory (BAT) (Reiter, 2001) is of the form

$$\Sigma \cup \mathcal{D}_{ss} \cup \mathcal{D}_{ap} \cup \mathcal{D}_{una} \cup \mathcal{D}_{S0}, \quad (8.10)$$

where
• \( \Sigma \) is the conjunction of the foundational axioms (8.4) - (8.6);

• \( D_{sa} \) is a conjunction of successor state axioms of the form

\[
F(x, do(a, s)) \leftrightarrow \Phi_F(x, a, s),
\]

where \( \Phi_F(x, a, s) \) is a formula that is uniform in \( s \) and whose free variables are among \( x, a, s \);

• \( D_{ap} \) is a conjunction of action precondition axioms of the form

\[
Poss(A(x), s) \leftrightarrow \Pi_A(x, s),
\]

where \( \Pi_A(x, s) \) is a formula that is uniform in \( s \) and whose free variables are among \( x, s \);

• \( D_{una} \) is the conjunction of unique name axioms for fluents and actions;

• \( D_{S0} \) is a conjunction of first-order formulas that are uniform in \( S_0 \).

Reformulating Basic Action Theories in the First-Order Stable Model Semantics

Similar to the reformulation of Lin’s causal theories (Chapter 8.1), we use \( D_{sit} \) instead of the second-order axiom (8.6). The following theorem shows how a BAT (8.10) can be viewed under the first-order stable model semantics.

**Theorem 25** Given a BAT \( T \), let \( T^- \) be the theory obtained by dropping (8.6) from \( T \). Then, \( T \) is equivalent to the following theories if we disregard the predicate \( Sit \):

(a) \( SM[D_{sit}; Sit] \land T^- \);

(b) \( SM[D_{sit} \land T^- ; Sit] \).

As before, the proof of the equivalence of (a) and (b) uses the splitting theorem (Theorem 12, Chapter 4.1).
In the rest of this section, we consider an alternative encoding of BAT in ASP, in which we do not need to provide explicit successor state axioms $D_{ss}$. Instead, the successor state axioms are entailed by the effect axioms and the generic inertia axioms adopted in ASP by making both the positive predicate $\text{Holds}$ and the negative predicate $\sim\text{Holds}$ intensional (Chapter 3.2). In the following, we assume that the underlying signature contains both these predicates. Also, for simplicity, we disregard the second-order axiom (8.6).

An ASP-style BAT is of the form

$$\Sigma \cup D_{\text{effect}} \cup D_{\text{precond}} \cup D_{\text{inertia}} \cup D_{\text{exogenous}} \cup D_{\text{una}} \cup D_{S_0}$$  \hspace{1cm} (8.11)

where

- $\Sigma, D_{\text{una}}$ and $D_{S_0}$ are defined the same as before;
- $D_{\text{effect}}$ is a conjunction of axioms of the form
  $$\gamma_R^+(x, a, s) \rightarrow \text{Holds}(R(x), \text{do}(a, s))$$  \hspace{1cm} (8.12)
  or
  $$\gamma_R^-(x, a, s) \rightarrow \sim\text{Holds}(R(x), \text{do}(a, s)),$$  \hspace{1cm} (8.13)
where $\gamma_R^+(x, a, s)$ and $\gamma_R^-(x, a, s)$ are formulas that are uniform in $s$ and whose free variables are among $x, a$ and $s$;
- $D_{\text{precond}}$ is a conjunction of axioms of the form
  $$\pi_A(x, s) \rightarrow \text{Poss}(A(x), s)$$  \hspace{1cm} (8.14)
where $\pi_A(x, s)$ is a formula that is uniform in $s$ and whose free variables are among $x, s$;
- $D_{\text{inertia}}$ is the conjunction of the axioms
  $$\text{Holds}(R(x), s) \land \sim\text{Holds}(R(x), \text{do}(a, s)) \rightarrow \text{Holds}(R(x), \text{do}(a, s)),$$
  $$\sim\text{Holds}(R(x), s) \land \sim\text{Holds}(R(x), \text{do}(a, s)) \rightarrow \sim\text{Holds}(R(x), \text{do}(a, s))$$
for all fluent names $R$;

- $\mathcal{D}_{\text{exogenous}}$ is the conjunction of

$$
\text{Holds}(R(x), S_0) \lor \sim \text{Holds}(R(x), S_0)
$$

for all fluent names $R$.

Note that axioms in $\mathcal{D}_{\text{inertia}}$ are typically used in answer set programming to represent the common sense law of inertia (Lifschitz & Turner, 1999). Similarly, $\mathcal{D}_{\text{exogenous}}$ is used to represent that the initial value of a fluent is arbitrary.\(^4\)

We will show how this ASP-style BAT is related to Reiter’s BAT. First, since we use strong negation, it is convenient to define the following notions. For the signature $\sigma$ of a given BAT, $\sigma^\text{Holds}$ is the signature obtained by adding $\sim \text{Holds}$ to $\sigma$. We say that an interpretation $I$ of $\sigma^\text{Holds}$ is \textit{complete} on $\text{Holds}$ if it satisfies

$$
\forall y (\text{Holds}(y) \lor \sim \text{Holds}(y))
$$

where $y$ is a list of distinct variables. Given an interpretation $I$ of $\sigma^\text{Holds}$, expression $I|_\sigma$ denotes the projection of $I$ on $\sigma$.

Let $\mathcal{D}_{\text{ss}}$ be the conjunction of successor state axioms

$$
\text{Holds}(R(x), do(a, s)) \leftrightarrow \Gamma_R^+(x, a, s) \lor (\text{Holds}(R(x), s) \land \neg \Gamma_R^-(x, a, s))
$$

where $\Gamma_R^+(x, a, s)$ is the disjunction of $\gamma_R^+(x, a, s)$ for all axioms (8.12) in $\mathcal{D}_{\text{effect}}$, and $\Gamma_R^-(x, a, s)$ is the disjunction of $\gamma_R^-(x, a, s)$ for all axioms (8.13) in $\mathcal{D}_{\text{effect}}$. By $\mathcal{D}_{\text{ap}}$ we denote the conjunction of axioms

$$
\text{Poss}(A(x), s) \leftrightarrow \Pi_A(x, s)
$$

where $\Pi_A(x, s)$ is the disjunction of $\pi_A(x, s)$ for all axioms (8.14) in $\mathcal{D}_{\text{precond}}$.

4The axioms $\mathcal{D}_{\text{inertia}}$ and $\mathcal{D}_{\text{exogenous}}$ are also closely related to the translation of $\mathcal{C}^+$ into non-monotonic causal logic (Giunchiglia et al., 2004).
Theorem 26  Let $T$ be a theory (8.11) of signature $\sigma^{Holds}$, and $I$ a coherent interpretation of $\sigma^{Holds}$ that is complete on $Holds$. If $I$ satisfies

$$
-\exists x a s (\Gamma_R^+(x, a, s) \land \Gamma_R^-(x, a, s))
$$

for every fluent name $R$, then $I$ satisfies

$$SM[T; Poss, Holds, \sim Holds]$$

iff $I|_\sigma$ satisfies the BAT

$$\Sigma \land D_{ss} \land D_{ap} \land D_{una} \land D_{S_0}.$$

Reformulating Basic Action Theories in Answer Set Programming

Since a BAT $T$ (not including the second-order axiom (8.6)) can be viewed as a first-order formula under the stable model semantics (with the list of intensional predicates being empty), it follows that F2LP can be used to turn $T \cup \Pi_{situation}$ into a logic program. As before, we focus on the ASP-style BAT.

Theorem 27  Let $T$ be an ASP-style BAT (8.11) of signature $\sigma$ that contains finitely many predicate constants, and let $F$ be the FOL-representation of the program obtained from $T$ by applying translation F2LP with intensional predicates

$\{Holds, \sim Holds, Poss\}$. Then $SM[T; Holds, \sim Holds, Poss]$ is $\sigma$-equivalent to $SM[F]$.

Consider the “broken object” example discussed in (Reiter, 1991). An object is broken if it is fragile and someone drops it, or if a bomb next to it explodes. Also, it is no longer broken if a person repairs it. Figure 8.2 shows an encoding of the example in the language of F2LP. Consider the simple projection problem of determining if an object $o$, which is next to bomb $b$, is broken after the bomb explodes. We add $\Pi_{executable}$ and the following formulas to the theory in Figure 8.2.
% initial situation
-h(broken(o),s0) & h(fragile(o),s0) & h(nexto(b,o),s0).
-h(holding(p,o),s0) & -h(exploded(b),s0).

% query
-(executable(do(explode(b),s0)) & h(broken(o),do(explode(b),s0))).

$ f2lp broken | gringo -c maxdepth=1 | claspD

returns no answer set as expected.
% File: broken
% domains other than situations
person(p).  object(o).  bomb(b).

#domain person(R).
#domain object(Y).
#domain bomb(B).

fluent(holding(R,Y)).  fluent(nexto(B,Y)).  fluent(fragile(Y)).
fluent(broken(Y)).  fluent(exploded(B)).

action(drop(R,Y)).  action(explode(B)).  action(repair(R,Y)).

#domain fluent(F).  #domain action(A).

depth(0..maxdepth).  #domain depth(L).

% defining the situation domain
nesting(0,s0).
nesting(L,S) & L < maxdepth -> nesting(L+1,do(A,S)).
nesting(L,S) -> situation(S).
nesting(maxdepth,S) -> final(S).

% Effect Axioms
situation(S) & h(fragile(Y),S) & -final(S) ->
    h(broken(Y),do(drop(R,Y),S)).
situation(S) & h(nexto(B,Y),S) & -final(S) ->
    h(broken(Y),do(explode(B),S)).
situation(S) & -final(S) -> h(exploded(B),do(explode(B),S)).
situation(S) & -final(S) -> ~h(broken(Y),do(repair(R,Y),S)).
situation(S) & -final(S) -> ~h(holding(R,Y),do(drop(R,Y),S)).

% Action precondition axioms
h(holding(R,Y),S) & situation(S) -> poss(drop(R,Y),S).
situation(S) & -h(exploded(B),S) -> poss(explode(B),S).
situation(S) & h(broken(Y),S) -> poss(repair(R,Y),S).

% inertial axioms
h(F,S) & ~h(F,do(A,S)) & situation(S) & -final(S) -> h(F,do(A,S)).
~h(F,S) & -h(F,do(A,S)) & situation(S) & -final(S) -> ~h(F,do(A,S)).

% D_exogeneous_0
h(F,s0) | ~h(F,s0).

% Consider only those interpretations that are complete on Holds
-h(F,S) & ~h(F,S) & situation(S) -> false.

Figure 8.2: “Broken object” example in F2LP

8.3 Handling Recursive Axioms in the Situation Calculus

Chapter 7.4 shows an example of how event calculus theories can be enhanced with expressive ASP rules. Here, we show another advantage of ASP-based reasoning for circumscriptive action theories, particularly, the ability to handle recursive axioms.

Consider an extension of the Lin’s suitcase example discussed in (Lin, 1995). In this extension, a new fluent \textit{down}, which is the opposite of \textit{up}, is introduced, and the following indirect effects of \textit{flip} are added:

\[
\begin{align*}
\text{caused}(\text{up}(X), t, S) &\land \text{situation}(S) \rightarrow \text{caused}(\text{down}(X), f, S). \\
\text{caused}(\text{up}(X), f, S) &\land \text{situation}(S) \rightarrow \text{caused}(\text{down}(X), t, S). \\
\text{caused}(\text{down}(X), t, S) &\land \text{situation}(S) \rightarrow \text{caused}(\text{up}(X), f, S). \\
\text{caused}(\text{down}(X), f, S) &\land \text{situation}(S) \rightarrow \text{caused}(\text{up}(X), t, S).
\end{align*}
\]

As mentioned in (Lin, 1995), Clark’s completion cannot be applied to the resulting theory because of the recursion between the fluents \textit{up} and \textit{down}. As a result, the existing reasoners cannot handle these axioms. However, these axioms can be handled using our ASP-based approach. For example, if both the locks are down in the initial situation, one can verify that after flipping the first lock, the first lock is up and the second lock is down, by adding $\Pi_{\text{executable}}$ and the following formulas to the theory in Figure 8.1.

\[
\begin{align*}
% \text{fluent 'down'} \\
\text{fluent}(\text{down}(X)). \\
%
\text{more indirect effects} \\
\text{caused}(\text{up}(X), t, S) &\land \text{situation}(S) \rightarrow \text{caused}(\text{down}(X), f, S). \\
\text{caused}(\text{up}(X), f, S) &\land \text{situation}(S) \rightarrow \text{caused}(\text{down}(X), t, S). \\
\text{caused}(\text{down}(X), t, S) &\land \text{situation}(S) \rightarrow \text{caused}(\text{up}(X), f, S). \\
\text{caused}(\text{down}(X), f, S) &\land \text{situation}(S) \rightarrow \text{caused}(\text{up}(X), t, S).
\end{align*}
\]

130
caused(down(X),f,S) & situation(S) -> caused(up(X),t,S).

% a lock has to be either in the up or down position
h(up(X),S) & h(down(X),S) & situation(S) -> false.
-h(up(X),S) & -h(down(X),S) & situation(S) -> false.

% initial situation
h(down(l1),s0).
h(down(l2),s0).

% query
- ( executable(do(flip(l1),s0)) &
   h(up(l1),do(flip(l1),s0)) & h(down(l2),do(flip(l1),s0)) )).

$ f2lp suitcase | gringo -c maxdepth=1 | claspD

returns no answer set as expected.

8.4 Related Work

Prolog provides a natural implementation for basic action theories since
definitional axioms can be represented by Prolog rules according to the Clark’s
theorem (Reiter, 2001, Chapter 5). The Lloyd-Topor transformation that is used to
turn formulas into Prolog rules is similar to translation F2LP, but the difference is in
that the former preserves the completion semantics and the latter the stable model
semantics.

Lin and Wang (1999) describe a language that can be used to represent a
syntactically restricted form of Lin’s causal theories, called “clausal causal
theories,” which do not allow quantifiers. They show how to translate that language
into answer set programs with strong negation, the answer sets of which are then
used to obtain fully instantiated successor state axioms and action precondition.
axioms. This is fundamentally different from our approach, which computes the
propositional models of the full situation calculus theories directly.

Kautz and Selman (1992) introduced linear encodings that are similar to a
propositionalized version of the situation calculus (McCarthy & Hayes, 1969). Lin
(2003) introduced an action description language and presented a procedure to
compile an action domain in that language into a complete set of successor state
axioms, from which a STRIPS-like description can be extracted. This procedure is
implemented in the system CCS\(^5\). The soundness of the procedure is shown with
respect to a translation from action domain descriptions into Lin’s causal theories.
However, that procedure is based on completion and so, unlike our approach,
cannot handle recursive axioms.

8.5 Proofs

*Proof of Theorem 23*

*Between (a) and (b):* Since \(D_{caused}\) is canonical relative to \(Caused\), by
Theorem 4, (a) is equivalent to

\[
SM[D_{caused}; Caused] \land D_{pos} \land D_{rest} \land (8.6). \tag{8.15}
\]

Consequently, it is sufficient to prove the claim that, under the assumption
\(\forall s \ Sit(s)\), formula (8.6) is equivalent to \(SM[D_{sit}; Sit]\).

First note that under the assumption, (8.6) can be equivalently rewritten as

\[
\forall p (p(S_0) \land \forall a, s(p(s) \rightarrow p(do(a, s))) \rightarrow p = Sit). \tag{8.16}
\]

On the other hand, under \(\forall s \ Sit(s)\), \(SM[D_{sit}; Sit]\) is equivalent to

\[
Sit(S_0) \land \forall a, s(Sit(s) \rightarrow Sit(do(a, s))) \\
\land \forall p (p < Sit \rightarrow \neg(p(S_0) \land \forall a, s(p(s) \rightarrow p(do(a, s)))) \land \forall a, s(Sit(s) \rightarrow Sit(do(a, s))))).
\]

\(^5\)http://www.cs.ust.hk/~flyn/ccp.html
which, under the assumption $\forall s \text{Sit}(s)$, is equivalent to
\[
\forall p \left( p(S_0) \land \forall a, s(p(s) \rightarrow p(do(a, s)) \rightarrow \text{Sit} \leq p) \right)
\]
and furthermore to (8.16).

**Between (b) and (c):** Since $\phi(s)$ does not contain Poss, the equivalence follows from the relation between completion and the first-order stable model semantics (Theorem 3).

**Between (c) and (d):** Since $D_{\text{caused}}$ contains no strictly positive occurrence of Poss and $D_{\text{poss} \rightarrow}$ contains no occurrence of Caused, every strongly connected component in the predicate dependency graph (Chapter 3.2) of $D_{\text{caused}} \land D_{\text{poss} \rightarrow}$ relative to \{Caused, Poss\} either belongs to Caused or belongs to Poss. By Theorem 12, it follows that (c) is equivalent to
\[
\text{SM}[D_{\text{caused}} \land D_{\text{poss} \rightarrow}; \text{Caused, Poss}] \land D_{\text{rest}}^{-} \land \text{SM}[D_{\text{sit}}; \text{Sit}].
\]
Similarly, applying Theorem 12 two more times, we get that the above formula is equivalent to (d).

**Proof of Theorem 24**

Since (8.9) is almost universal relative to \{Caused, Poss, Sit\}, the result follows from Theorems 16 and 23.

**Proof of Theorem 25**

As shown in the proof of Theorem 23, formula (8.6) is equivalent to $\text{SM}[D_{\text{sit}}; \text{Sit}]$ under the assumption $\forall s \text{Sit}(s)$. So, $T$ is equivalent to $\text{SM}[D_{\text{sit}}; \text{Sit}] \land T^{-}$ if we disregard Sit.

Since Sit does not occur in $T^{-}$, and since $D_{\text{sit}}$ contains no occurrence of any predicate other than Sit, the equivalence between (a) and (b) follows from Theorem 12.
Proof of Theorem 26

Theory \( T \) is

\[ \Sigma \land \mathcal{D}_{\text{effect}} \land \mathcal{D}_{\text{precond}} \land \mathcal{D}_{S_0} \land \mathcal{D}_{\text{unda}} \land \mathcal{D}_{\text{inertia}} \land \mathcal{D}_{\text{exogenous}0}, \]

and the corresponding BAT is

\[ \Sigma \land \mathcal{D}_{ss} \land \mathcal{D}_{ap} \land \mathcal{D}_{S_0} \land \mathcal{D}_{\text{unda}}. \]

Without loss of generality, we assume that \( T \) is already equivalently rewritten so that there is exactly one positive effect axiom and exactly one negative effect axiom for each fluent \( R \), and that there is exactly one action precondition axiom for each action \( A \).

Consider

\[ \text{SM}[(\Sigma \land \mathcal{D}_{\text{effect}} \land \mathcal{D}_{\text{precond}} \land \mathcal{D}_{S_0} \land \mathcal{D}_{\text{unda}} \land \mathcal{D}_{\text{inertia}} \land \mathcal{D}_{\text{exogenous}0} \land \mathcal{D}_{\text{unda}}; \text{Poss}, \text{Holds}, \sim \text{Holds}]. \]

Since \( \Sigma \) and \( \mathcal{D}_{\text{unda}} \) are negative on the intensional predicates, the formula is equivalent to

\[ \text{SM}[(\mathcal{D}_{\text{effect}} \land \mathcal{D}_{\text{precond}} \land \mathcal{D}_{S_0} \land \mathcal{D}_{\text{unda}} \land \mathcal{D}_{\text{inertia}} \land \mathcal{D}_{\text{exogenous}0}; \text{Poss}, \text{Holds}, \sim \text{Holds}] \land \Sigma \land \mathcal{D}_{\text{unda}}. \]

Since \( \text{Poss} \) does not occur in

\[ \mathcal{D}_{\text{effect}} \land \mathcal{D}_{S_0} \land \mathcal{D}_{\text{inertia}} \land \mathcal{D}_{\text{exogenous}0}, \]

and since \( \mathcal{D}_{\text{precond}} \) is negative on \( \{\text{Holds}, \sim \text{Holds}\} \), by Theorem 12, (8.17) is equivalent to

\[ \text{SM}[(\mathcal{D}_{\text{effect}} \land \mathcal{D}_{S_0} \land \mathcal{D}_{\text{inertia}} \land \mathcal{D}_{\text{exogenous}0}; \text{Holds}, \sim \text{Holds}] \land \text{SM}[\mathcal{D}_{\text{precond}}; \text{Poss}] \land \Sigma \land \mathcal{D}_{\text{unda}}, \]

(8.18)
which is equivalent to
\[
\text{SM}[D_{\text{effect}} \land D_{S_0} \land D_{\text{inertia}} \land D_{\text{exogenous}0}; \text{Holds}, \neg\text{Holds}]
\land D_{\text{ap}} \land \Sigma \land D_{\text{ana}}.
\]

Therefore the statement of the theorem can be proven by showing the following: if
\[
I \models \neg \exists x a s (\Gamma_R^+(x, a, s) \land \Gamma_R^-(x, a, s))
\]  
(8.19)
for every fluent \( R \), and
\[
I \models \Sigma
\]  
(8.20)
then \( I \) satisfies
\[
\text{SM}[D_{S_0} \land D_{\text{exogenous}0} \land D_{\text{effect}} \land D_{\text{inertia}}; \text{Holds}, \neg\text{Holds}]
\]  
(8.21)
iff \( I|_\sigma \) satisfies
\[
D_{S_0} \land D_{ss}.
\]

From \( D_{\text{exogenous}0} \), it follows that (8.21) is equivalent to
\[
\text{SM}[D_{S_0}^- \land D_{\text{exogenous}0} \land D_{\text{effect}} \land D_{\text{inertia}}; \text{Holds}, \neg\text{Holds}],
\]  
(8.22)
where \( D_{S_0}^- \) is the formula obtained from \( D_{S_0} \) by prepending \( \neg \neg \) to all occurrences of \( \text{Holds} \). Under the assumption (8.20),
\[
D_{S_0}^- \land D_{\text{exogenous}0} \land D_{\text{effect}} \land D_{\text{inertia}}
\]
is atomic-tight w.r.t. \( I \) on \( \text{Holds} \), \(^6\) so that by the relationship between completion and \( \text{SM} \) that is stated in Corollary 3 of (Lee & Meng, 2011), we have that
\( I \models (8.22) \) iff \( I \) satisfies \( D_{S_0} \), and, for each fluent \( R \),
\[
\text{Holds}(R(x), do(a, s)) \leftrightarrow \Gamma_R^+(x, a, s) \lor (\text{Holds}(R(x, s) \land \neg \neg \text{Holds}(R(x), do(a, s))))
\]  
(8.23)

\(^6\)See Section 4.1 of (Lee & Meng, 2011) for the definition.
\[ \sim \text{Holds}(R(x), do(a, s)) \leftrightarrow \Gamma^{-}_{R}(x, a, s) \lor (\sim \text{Holds}(R(x), s) \land \sim \text{Holds}(R(x), do(a, s))) \]  

(8.24)

where \( x, a, s \) are any (lists of) object names of corresponding sorts.

It remains to show that, under the assumption (8.19), \( I \) satisfies

(8.23) \( \land \) (8.24) iff \( I|_{\sigma} \) satisfies

\[ \text{Holds}(R(x), do(a, s)) \leftrightarrow \Gamma^{+}_{R}(x, a, s) \lor (\text{Holds}(R(x), s) \land \sim \Gamma^{-}_{R}(x, a, s)). \]  

(8.25)

In the following we will use the following facts.

- \( I \models \sim \text{Holds}(R(x), s) \) iff \( I|_{\sigma} \notmodels \text{Holds}(R(x), s) \).
- If \( F \) is a ground formula that does not contain \( \sim \), then \( I \models F \) iff \( I|_{\sigma} \models F \).

**Left to Right:** Assume \( I \models (8.23) \land (8.24) \).

- **Case 1:** \( I|_{\sigma} \models \text{Holds}(R(x), do(a, s)) \). Clearly, \( I \models \text{Holds}(R(x), do(a, s)) \), so that, from (8.23), there are two subcases to consider.
  - **Subcase 1:** \( I \models \Gamma^{+}_{R}(x, a, s) \). Clearly, \( I|_{\sigma} \) satisfies both LHS and RHS of (8.25).
  - **Subcase 2:** \( I \models \text{Holds}(R(x), s) \). From (8.24), it follows that \( I \notmodels \Gamma^{-}_{R}(x, a, s) \), and consequently, \( I|_{\sigma} \notmodels \Gamma^{-}_{R}(x, a, s) \). Clearly, \( I|_{\sigma} \) satisfies both LHS and RHS of (8.25).

- **Case 2:** \( I|_{\sigma} \notmodels \text{Holds}(R(x), do(a, s)) \). It follows from (8.23) that \( I \notmodels \Gamma^{+}_{R}(x, a, s) \), which is equivalent to saying that \( I|_{\sigma} \notmodels \Gamma^{+}_{R}(x, a, s) \). Also since \( I \models \sim \text{Holds}(R(x), do(a, s)) \), from (8.24), there are two subcases to consider.
Subcase 1: $I \models \Gamma_R^{-}(x, a, s)$. Clearly, $I|_{\sigma}$ satisfies neither LHS nor RHS of (8.25).

Subcase 2: $I \models \sim \text{Holds}(R(x), s)$. This is equivalent to saying that $I|_{\sigma} \not\models \text{Holds}(R(x), s)$. Clearly, $I|_{\sigma}$ satisfies neither LHS nor RHS of (8.25).

Right to Left: Assume $I|_{\sigma} \models (8.25)$.

• Case 1: $I \models \text{Holds}(R(x), do(a, s))$. It follows from (8.25) that $I|_{\sigma}$ satisfies RHS of (8.25), so that there are two subcases to consider.

  Subcase 1: $I|_{\sigma} \models \Gamma_R^{+}(x, a, s)$. Clearly, $I$ satisfies both LHS and RHS of (8.23). Also from (8.19), it follows that $I \not\models \Gamma_R^{-}(x, a, s)$. Consequently, $I$ satisfies neither LHS nor RHS of (8.24).

  Subcase 2: $I|_{\sigma} \models \text{Holds}(R(x), s) \land \sim \Gamma_R^{-}(x, a, s)$. Clearly, $I$ satisfies both LHS and RHS of (8.23). Since $I \not\models \Gamma_R^{-}(x, a, s)$, $I$ satisfies neither LHS nor RHS of (8.24).

• Case 2: $I \models \sim \text{Holds}(R(x), do(a, s))$. It follows from (8.25) that $I|_{\sigma} \not\models \Gamma_R^{+}(x, a, s)$, and $I|_{\sigma} \not\models (\text{Holds}(R(x), s) \land \sim \Gamma_R^{-}(x, a, s))$. From the latter, consider the two subcases.

  Subcase 1: $I|_{\sigma} \not\models \text{Holds}(R(x), s)$. Clearly, $I$ satisfies neither LHS nor RHS of (8.23), and satisfies both LHS and RHS of (8.24).

  Subcase 2: $I|_{\sigma} \not\models \sim \Gamma_R^{-}(x, a, s)$. Clearly, $I$ satisfies neither LHS nor RHS of (8.23), and satisfies both LHS and RHS of (8.24).
Proof of Theorem 27

From $\mathcal{D}_{\text{exogenous}0}$, it follows that $\text{SM}[T; \text{Holds}, \neg\neg\text{Holds}, \text{Poss}]$ is equivalent to $\text{SM}[T\neg\neg; \text{Holds}, \neg\neg\text{Holds}, \text{Poss}]$, where $T\neg\neg$ is obtained from $T$ by prepending $\neg\neg$ to all occurrences of $\text{Holds}$ in $\mathcal{D}_{S_0}$. From the definition of a uniform formula (Reiter, 2001), it follows that $T\neg\neg$ is almost universal relative to $\{\text{Holds}, \neg\neg\text{Holds}, \text{Poss}\}$.

The result follows from Theorem 16. □
In this chapter, we use the results from Chapters 3-5 to reformulate Temporal Action Logics (TAL) in the first-order stable model semantics and in ASP. Based on the reformulation, we show how F2LP can be used to compute descriptions in TAL. We then show how constraint answer set solvers, which are answer set solvers enhanced with constraint processing techniques, can be used for reasoning with TAL, and discuss some of the advantages of this approach. Finally, we compare our ASP-based reasoner with VITAL\(^1\), which is a well-known tool for reasoning about actions using TAL.

9.1 Review of Temporal Action Logics

This review is based on (Doherty & Kvarnström, 2008) and Chapter 2 of (Kvarnström, 2005).

A narrative in TAL is specified using the language \(L(ND)\), which is referred to as the surface language. The language is many-sorted, consisting of a number of value sorts \(V_i\), a number of feature sorts \(F_i\), an action sort \(A\), and a temporal sort \(T\). The boolean sort \(B\) is a value sort with constants \{true, false\}. Each feature sort is associated with a value sort such that \(\text{dom}(F_i) = V_j\) for some \(j\).

A temporal term, often denoted by \(t\) or \(t_i\) or \(t'\), is a variable, or a constant, or an expression of the form \(t_1 + t_2\), all of sort \(T\). A value term, often denoted by \(\omega\) or \(\omega_i\), is a variable or constant of some value sort \(V_i\), an expression \(\text{value}(t, f)\) where \(f\) is a fluent term, or an expression \(g(\omega_1, \ldots, \omega_n)\) where \(g: V_1 \times \cdots \times V_n \mapsto V_i\) is a value function symbol. The function \(\text{value}(t, f)\) returns the value of the fluent \(f\) at timepoint \(t\).

\(^1\)http://www.ida.liu.se/~jonkv/vital
A fluent term is a feature variable or a feature expression of the form \( f(\omega_1, \ldots, \omega_n) \) where \( f : V_1 \times \cdots \times V_n \mapsto F_i \) is a feature symbol. An action term is an expression of the form \( A(\omega_1, \ldots, \omega_n) \) where \( A : V_1 \times \cdots \times V_n \mapsto A \) is an action symbol. In the following, \( f \) and \( g \) are fluent terms, and \( a \) is an action term.

A temporal formula is any comparison between two temporal terms. A value formula is of the form \( \omega_1 = \omega_2 \), or \( r(\omega_1, \ldots, \omega_n) \) where \( r : V_1 \times \cdots \times V_n \mapsto A \) is a relation symbol. An elementary fluent formula is an expression of the form \( f \equiv \omega \). A fluent formula is an elementary fluent formula or a combination of fluent formulas formed with the standard logical connectives and quantification over values. The formulas \( f \equiv \text{true} \) and \( f \equiv \text{false} \) can be abbreviated as \( f \) and \( \neg f \) respectively.

A timed formula is any of the following, where \( \alpha \) is a fluent formula:

- fixed fluent formula: \([t, t']\alpha, (t, t')\alpha, [t, \infty)\alpha, (t, \infty)\alpha, \) and \([t]\alpha\).
- fluent change formula: \( C_T([t]\alpha), C_F([t]\alpha), \) and \( C([t]\alpha) \).
- reassignment formulas: \( R([t, t']\alpha), R((t, t')\alpha), R([t, t']\alpha), R((t, t')\alpha), \) and \( R([t]\alpha) \).
- interval reassignment formulas: \( I([t, t']\alpha), I((t, t')\alpha), I([t, t']\alpha), I((t, t')\alpha), \) and \( I([t]\alpha) \).
- occlusion formulas: \( X([t, t']\alpha), X((t, t')\alpha), X([t, t']\alpha), X((t, t')\alpha), \) and \( X([t]\alpha) \).

A static formula is a temporal formula, a value formula, a fixed fluent formula, a fluent change formula, \( \top, \bot, \) or a combination of static formulas formed using the standard logical connectives together with quantification over values and time. A change formula is a formula of the form \( Q^\pi(\alpha_1 \lor \cdots \lor \alpha_n) \) where \( Q^\pi \) is a sequence of quantifiers with variables, and each \( \alpha_i \) is a conjunction of static,
occlusion and reassignment formulas. A change formula is balanced if it satisfies the following conditions:

- whenever a fluent term $f(\omega_1, \ldots, \omega_m)$ appears inside a reassignment or occlusion formula in one of the disjuncts $\alpha_i$, it must also appear every other $\alpha_j$ inside a reassignment or occlusion formula with exactly the same temporal argument.

- any existentially quantified variable $v$ in the formula, whenever appearing inside a reassignment or occlusion formula, only does so in a formula $f \models v$.

An application formula is (a) a balanced change formula, or (b) a formula of the form $F \rightarrow G$ where $F$ is a static formula and $G$ is a balanced change formula, or a combination of formulas of the form (a) and (b) formed with conjunction and universal quantification over values and time. An occurrence formula is of the form $[t, t'] \Psi$ where $\Psi$ is an action term. Finally, a persistence formula is an expression of the form $Per(t, f)$, or $Dur(t, f, \omega)$, or a combination of persistence formulas formed with conjunction and universal quantification over values and time.

A TAL narrative is formed using the following statements:

- **action type specification** (labeled acs): $[t, t'] \Psi \rightarrow \phi$ where $\Psi$ is an action term and $\phi$ is an application formula.

- **dependency constraint** (labeled dep): an application formula.

- **domain constraint** (labeled dom): a static formula.

- **persistence statement** (labeled per): a persistence formula.

- **observation statement** (labeled obs): a static formula.
• action occurrence statement (labeled occ): a variable-free occurrence formula.

Reasoning about a narrative is done by translating it into the base language \( L(FL) \), which is an order-sorted classical first-order language with equality using a linear discrete time structure. The language uses the ternary predicates \( \text{Holds} \) and \( \text{Occurs} \), and the binary predicate \( \text{Occlude} \). \( \text{Holds}(t, f, \omega) \) represents that fluent \( f \) has value \( \omega \) at time \( t \). \( \text{Occlude}(t, f) \) represents that a persistent or durational fluent \( f \) is exempt from inertia or default value assumption, respectively, at time \( t \). \( \text{Occurs}(t, t', a) \), represents that action \( a \) occurs during the time interval \([t, t']\). The translation from \( L(ND) \) to \( L(FL) \) is given by the function \( \text{Trans} \), that is defined as follows (\( \overline{\omega} \) represents a list of value terms, \( \odot \in \{\land, \lor, \to\} \) and \( Q \in \{\forall, \exists\} \)):

- \( \text{Trans}(\top) = \top; \text{Trans}(\bot) = \bot; \)

- \( \text{Trans}([t]f(\overline{\omega}) = \text{Holds}(t, f(\overline{\omega}), \omega); \)
  \( \text{Trans}(\text{X}([t]f(\overline{\omega}))) = \text{Occlude}(t, f(\overline{\omega})); \)
  \( \text{Trans}([t, t']a) = \text{Occurs}(t, t', a); \)

- \( \text{Trans}(\text{Per}(t', f)) = \)
  \( \forall t(t' = t + 1 \land \neg\text{Occlude}(t + 1, f) \to \forall v(\text{Holds}(t + 1, f, v) \leftrightarrow \text{Holds}(t, f, v))); \)
  \( \text{Trans}(\text{Dur}(t, f, \omega)) = \neg\text{Occlude}(t, f) \to \text{Holds}(t, f, \omega); \)

- \( \text{Trans}(\alpha \odot \beta) = \text{Trans}(\alpha) \odot \text{Trans}(\beta); \) similar for \( \neg \);
  \( \text{Trans}(Qv(\alpha)) = Qv\text{Trans}(\alpha); \)

- \( \text{Trans}([t] \alpha \odot \beta) = \text{Trans}([t]\alpha) \odot \text{Trans}([t]\beta); \) similar for \( \neg \) and quantifiers;

- \( \text{Trans}(X([t] \alpha \odot \beta)) = \text{Trans}(X([t]\alpha)) \land \text{Trans}(X([t]\beta)); \)
  \( \text{Trans}(X([t] \neg\alpha)) = \text{Trans}(X([t] \alpha)); \)
  \( \text{Trans}(X([t] Qv(\alpha))) = \forall v\text{Trans}(X([t]\alpha)); \)

- \( \text{Trans}([t_1, t_2] \alpha) = \forall t(t \geq t_1 \land t \leq t_2 \to \text{Trans}([t] \alpha)); \)
  \( \text{Trans}([t_1, \infty] \alpha) = \forall t(t \geq t_1 \to \text{Trans}([t] \alpha)); \)
\[ \text{Trans}(R([t_1, t_2] \alpha)) = \text{Trans}(X([t_1, t_2] \alpha)) \land \text{Trans}([t_2] \alpha); \]
\[ \text{Trans}(R([t] \alpha)) = \text{Trans}(X([t] \alpha)) \land \text{Trans}([t] \alpha); \]
\[ \text{Trans}(I([t_1, t_2] \alpha)) = \text{Trans}(X([t_1, t_2] \alpha)) \land \text{Trans}([t_1, t_2] \alpha); \]
\[ \text{Trans}(I([t] \alpha)) = \text{Trans}([t] \alpha) \land \text{Trans}([t] \alpha); \]

other forms of intervals are treated similarly;

- \[ \text{Trans}(C_T([t'] \alpha)) = \forall t'(t' = t + 1 \rightarrow \text{Trans}([t] \neg \alpha) \land \text{Trans}([t'] \alpha)); \]
- \[ \text{Trans}(C_F([t'] \alpha)) = \forall t'(t' = t + 1 \rightarrow \text{Trans}([t] \alpha) \land \text{Trans}([t'] \neg \alpha)); \]
- \[ \text{Trans}(C([t] \alpha)) = \text{Trans}(C_T([t] \alpha)) \lor \text{Trans}(C_F([t] \alpha)) \]

Consider any narrative \( N \) and let \( N_{\text{per}}, N_{\text{obs}}, N_{\text{occ}}, N_{\text{acs}}, N_{\text{domc}}, \) and \( N_{\text{depc}} \) denote the sets of persistence statements, observation statements, action occurrence statements, action type specifications, domain constraints, and dependency constraints in \( N \) respectively. The TAL domain description (referred to as preferred narrative) \( \Delta_N \) is given by

\[ \Gamma_{\text{fnd}} \land \Gamma_{\text{time}} \land \Gamma_{\text{per}} \land \Gamma_{\text{obs}} \land \Gamma_{\text{domc}} \land \text{CIR}[\Gamma_{\text{occ}}; \text{Occurs}] \land \text{CIR}[\Gamma_{\text{depc}} \land \Gamma_{\text{acs}}; \text{Occclude}] \]

(9.1)

where \( \Gamma_{\text{per}}, \Gamma_{\text{obs}}, \Gamma_{\text{occ}}, \Gamma_{\text{acs}}, \Gamma_{\text{domc}}, \) and \( \Gamma_{\text{depc}} \) are the formulas in \( L(FL) \) (first-order formulas) obtained by applying Trans on \( N_{\text{per}}, N_{\text{obs}}, N_{\text{occ}}, N_{\text{acs}}, N_{\text{domc}}, \) and \( N_{\text{depc}} \) respectively; \( \Gamma_{\text{fnd}} \) is the set of foundational axioms in \( L(FL) \), containing unique name axioms, unique value axioms, etc.; and \( \Gamma_{\text{time}} \) is the axiomatization of the particular temporal structure (linear and discrete) in \( L(FL) \).

9.2 Reformulating Temporal Action Logics in the First-Order Stable Model Semantics

Like in the cases of the event calculus and the situation calculus, this reformulation uses the concepts of canonical formulas and splitting, which were presented in Chapters 3.3 and 4 respectively.
Given a narrative $\mathcal{N}$ and the corresponding preferred narrative $\Delta_{\mathcal{N}}$, we can conclude the following:

(ob1) all occurrences of $\text{Occlude}$ in $\Gamma_{acs}$ and $\Gamma_{depc}$ are strictly positive, and there are no strictly positive occurrences of $\text{Occurs}$ in either of them;

(ob2) all occurrences of $\text{Occurs}$ in $\Gamma_{occ}$ are strictly positive, and there are no occurrences of $\text{Occlude}$ in it;

(ob3) $\Gamma_{dome}$, $\Gamma_{obs}$, $\Gamma_{fnd}$, and $\Gamma_{time}$ do not contain any occurrences of either $\text{Occlude}$ or $\text{Occurs}$; and

(ob4) all occurrences of $\text{Occlude}$ in $\Gamma_{per}$ are in the scope of negation, and there are no occurrences of $\text{Occurs}$ in it.

These observations lead us to the following theorem. In the following, we use $\Gamma_{ncirc}$ to denote $\Gamma_{fnd} \land \Gamma_{time} \land \Gamma_{per} \land \Gamma_{obs} \land \Gamma_{dome}$.

**Theorem 28** Given a TAL narrative $\mathcal{N}$ and the corresponding preferred narrative $\Delta_{\mathcal{N}}$ ((9.1)), the following formulas are logically equivalent:

(a) $\text{CIRC} [\Gamma_{occ}; \text{Occurs}] \land \text{CIRC} [\Gamma_{depc} \land \Gamma_{acs}; \text{Occlude}] \land \Gamma_{ncirc}$

(b) $\text{SM} [\Gamma_{occ}; \text{Occurs}] \land \text{SM} [\Gamma_{depc} \land \Gamma_{acs}; \text{Occlude}] \land \Gamma_{ncirc}$

(c) $\text{SM} [\Gamma_{occ} \land \Gamma_{depc} \land \Gamma_{acs} \land \Gamma_{ncirc}; \text{Occurs}, \text{Occlude}]$

The equivalence between (a) and (b) follows from Theorem 4, and observations (ob1) and (ob2) above which imply that $\Gamma_{occ}$ is canonical relative to $\text{Occurs}$ and $\Gamma_{depc} \land \Gamma_{acs}$ is canonical relative to $\text{Occlude}$. The equivalence between (b) and (c) follows from Theorem 12, and observations (ob1)-(ob4) above which imply that the conditions for applying the splitting theorem (Chapter 4.1) are satisfied.
9.3 Reformulating Temporal Action Logics in Answer Set Programming

Similar to the cases of the event calculus and the situation calculus, we use translation F2LP to turn formula $\Gamma_{occ} \land \Gamma_{depc} \land \Gamma_{acs} \land \Gamma_{ncirc}$, which is the formula within SM in Theorem 28(c) above, into the syntax of answer set programs.

Consider $\Gamma_{occ} \land \Gamma_{depc} \land \Gamma_{acs} \land \Gamma_{ncirc}$, where $\Gamma_{ncirc}$ is $\Gamma_{fnd} \land \Gamma_{time} \land \Gamma_{per} \land \Gamma_{obs} \land \Gamma_{domc}$. The only intensional predicates in these formulas are $\text{Occurs}$ and $\text{Occlude}$. Among the formulas, only $\Gamma_{depc}$, $\Gamma_{acs}$, and $\Gamma_{per}$ contain occurrences of $\text{Occlude}$, and only $\Gamma_{acs}$ and $\Gamma_{occ}$ contain occurrences of $\text{Occurs}$. From the definitions of an application formula and $\text{Trans}$, it follows that $\text{Occlude}$ is outside the scope of any positive occurrence of $\exists$ and any negative occurrence of $\forall$ in $\Gamma_{depc} \land \Gamma_{acs}$. Further, it is clear that all occurrences of $\text{Occlude}$ in $\Gamma_{per}$ are in the scope of negation, and that $\text{Occurs}$ is outside the scope of any positive occurrence of $\exists$ and any negative occurrence of $\forall$ in $\Gamma_{acs} \land \Gamma_{occ}$. This implies that $\Gamma_{occ} \land \Gamma_{depc} \land \Gamma_{acs} \land \Gamma_{ncirc}$ is almost universal relative to $\{\text{Occurs}, \text{Occlude}\}$, which in turn implies that translation F2LP can be used to turn the formula into the syntax of ASP. The following theorem makes this precise.

**Theorem 29** Let $F$ be the formula $\Gamma_{occ} \land \Gamma_{depc} \land \Gamma_{acs} \land \Gamma_{ncirc}$ of a signature $\sigma$, and let $F'$ be the FOL-representation of the program obtained from $F$ by applying translation F2LP with $\{\text{Occurs}, \text{Occlude}\}$ as the list of intensional predicates. Then, $SM[F; \text{Occurs}, \text{Occlude}]$ is $\sigma$-equivalent to $SM[F']$.

Consider the *Russian Airplane Hijack* (RAH) scenario as discussed in (Doherty & Kvarnström, 2008). This example demonstrates the capability of TAL in handling the ramification and qualification problems. In this scenario, three businessmen Boris, Erik, and Dimiter try to board a flight to Stockholm. Boris has a comb and a gun in his pocket, Dimiter is drunk, and Erik has a comb in his pocket.
When the businessmen move, the items in their pockets should move along with them. Similarly, when a plane flies from one location to another, the people inside should move along with the plane. Since Dimiter is drunk, he may not be able to board the plane. Finally, since Boris has a gun in his pocket, he should not be able to board the plane. The (partial) solutions provided to the ramification and qualification problems in TAL use dependency constraints. Following is part of the description provided with VITAL\(^2\) (v. 2.999.910 alpha), which is a well-known tool for reasoning about action and change using TAL. We only show the action type specifications and dependency constraints used in the description. These statements represent the direct effects, the ramifications, and the qualifications associated with the problem. The fluent \texttt{PossBoard(person, airplane)} is durational with default value \texttt{true}, and the rest of the fluents are persistent. The direct effects are represented by the following action type specifications:

\begin{align*}
\text{acs} [t_1, t_2] \textbf{Put}(person, pthing, pocket) & \rightarrow ( [t_1] \texttt{Loc(person) } \equiv \texttt{Loc(pthing)} \rightarrow \not R([t_1, t_2] \texttt{InPocket(person, pthing)})) \\
\text{acs} [t_1, t_2] \textbf{Travel}(person, loc_1, loc_2) & \rightarrow ( [t_1] \texttt{Loc(person) } \equiv loc_1 \rightarrow \not R([t_2] \texttt{Loc(person) } \equiv loc_2)) \\
\text{acs} [t_1, t_2] \textbf{Board}(person, airplane) & \rightarrow ( [t_1] \texttt{PossBoard(person, airplane)} \wedge \texttt{Loc(person) } \equiv \texttt{Airport} \rightarrow \not R([t_2] \texttt{Loc(person) } \equiv \texttt{Loc(airplane)} \wedge \texttt{OnPlane(airplane, person)})) \\
\text{acs} [t_1, t_2] \textbf{Fly}(airplane, runway_1, runway_2) & \rightarrow ( [t_1] \texttt{Loc(airplane) } \equiv \texttt{runway_1} \rightarrow \not I([t_2] \texttt{Loc(airplane) } \equiv \texttt{Air} \wedge R([t_2] \texttt{Loc(airplane) } \equiv \texttt{runway_2})))
\end{align*}

The qualification constraints are represented by the following dependency constraints:

\begin{align*}
\text{dep} [t] \texttt{InPocket(person, gun)} & \rightarrow I([t] \not \forall \texttt{airplane}(\neg \texttt{PossBoard(person, airplane)))) \\
\text{dep} [t] \texttt{Drunk(person)} & \rightarrow X ([t] \not \forall \texttt{airplane}(\neg \texttt{PossBoard(person, airplane))))
\end{align*}

\(^2\)\url{http://www.ida.liu.se/jonkv/vital/}
The ramification constraints are represented by the following dependency constraints:

\[ \text{dep } [t] \text{OnPlane}(\text{airplane, person}) \land C_T([t] \text{Loc}(\text{airplane}) = \text{loc}_3) \rightarrow \]
\[ R([t] \text{Loc}(\text{person}) = \text{Loc}(\text{airplane})) \]

\[ \text{dep } [t] \text{InPocket}(\text{person, pthing}) \land C_T([t] \text{Loc}(\text{person}) = \text{loc}_3) \rightarrow \]
\[ R([t] \text{Loc}(\text{pthing}) = \text{Loc}(\text{person})) \]

To compute the description using answer set solvers, we use system F2LP. Since F2LP does not accept input in the language of \( \mathcal{L}(\text{ND}) \), we need to encode the corresponding first-order theory directly. Figure 9.1 shows a complete F2LP encoding of the corresponding first-order theory.

The following command can be used to compute the answer sets of the theory:

\$ f2lp RAH | gringo -c maxstep=17 | claspD

The answer sets produce the expected results, including the following:

- \( \text{holds}(t, \text{loc}(\text{boris}), \text{airport}) \) for all \( t \geq 10 \): since boris has a gun in his pocket, he is unable to board the plane.

- \( \text{holds}(16, \text{loc}(\text{sas609}), \text{run609b}) \), \( \text{holds}(16, \text{onplane}(\text{sas609}, \text{erik}), \text{true}) \), \( \text{holds}(16, \text{loc}(\text{erik}), \text{run609b}) \), \( \text{holds}(16, \text{inpocket}(\text{erik}, \text{comb2}), \text{true}) \), \( \text{holds}(16, \text{loc}(\text{comb2}), \text{run609b}) \): since erik is on the plane and comb2 is in his pocket, the location of erik and comb2 is the same as the location of the plane, which is at the destination runway.

- some of the answer sets contain \( \text{holds}(16, \text{loc}(\text{dimiter}), \text{airport}) \) and others contain \( \text{holds}(16, \text{loc}(\text{dimiter}), \text{run609b}) \): since dimiter is drunk, he may or may not be able to board the plane.

\text{Figure 9.1: RAH example in F2LP}
9.4 Using Constraint Answer Set Solvers for Reasoning with Temporal Action Logics

Notice that the translation \( Trans \) involves turning formulas of the form \([t] f \equiv \omega \) into \( \text{Holds}(t, f, \omega) \). This could cause a grounding bottleneck for large domains. In order to avoid such bottlenecks, answer set solvers are being enhanced with constraint processing (CP) (Dechter, 2003; Rossi, Beek, & Walsh, 2006) techniques (see, for example, (Baselice, Bonatti, & Gelfond, 2005; Mellarkod, Gelfond, & Zhang, 2008; Gebser, Ostrowski, & Schaub, 2009)). As mentioned in the introduction, these enhancements can be carried over to ASP-based TAL reasoning. Here, we demonstrate how CLINGCON\(^3\) (Gebser et al., 2009), which combines the ASP solver CLINGO\(^4\) and the CP solver GECODE\(^5\), can be used for ASP-based TAL reasoning.

Intuitively, since \( \text{Holds} \) is non-intensional, we can simply replace \( \text{Holds}(t, f(x), \omega) \) in \( \Gamma_{\text{occ}} \land \Gamma_{\text{depc}} \land \Gamma_{\text{acs}} \land \Gamma_{\text{ncirc}} \), which is the formula within \( \text{SM} \) in Theorem 28(c), with \( f'(t, x) = \omega \), where \( f' \) is a function whose range is the same as the domain of the fluent \( f(x) \) and \( x \) is a list of terms. We can then apply translation F2LP on the resulting theory to turn it into an answer set program. We make the idea precise as follows. Consider a TAL narrative \( \mathcal{N} \) and any subset \( S \) of the set of feature symbols in \( \mathcal{N} \). If \( \sigma \) is the signature of the corresponding preferred narrative \( \Delta_{\mathcal{N}} \) ((9.1)), by \( \sigma^S \) we denote the signature obtained from \( \sigma \) by adding a function constant \( f' \) for every feature symbol \( f \) in \( S \). If a feature symbol \( f \) takes \( n \) arguments, then the arity of \( f' \) is \( n + 1 \). If \( F \) is the formula 
\[
\Gamma_{\text{occ}} \land \Gamma_{\text{depc}} \land \Gamma_{\text{acs}} \land \Gamma_{\text{ncirc}},
\]
by \( F^S \) we denote the formula of signature \( \sigma^S \) obtained from \( F \) by replacing every occurrence of \( \text{Holds}(t, f(x), \omega) \) in \( F \), where \( f \in S \), with

\(^3\)http://potassco.sourceforge.net/
\(^4\)http://potassco.sourceforge.net/
\(^5\)http://www.gecode.org/
\( f'(t, x) = \omega \). By \( EQ_S \) we denote the conjunction of formulas
\[
\forall t, x, v \left( \text{Holds}(t, f(x), v) \iff f'(t, x) = v \right)
\]
for every feature symbol \( f \) in \( S \).

**Theorem 30**  Given a TAL narrative \( \mathcal{N} \), let \( \sigma \) be the signature of the corresponding preferred narrative \( \Delta_{\mathcal{N}} \), and let \( F \) be the formula \( \Gamma_{occ} \land \Gamma_{depc} \land \Gamma_{acs} \land \Gamma_{ncirc} \). Then,

\[
SM[F; \text{Occurs}, \text{Occlude}]
\]

is \( \sigma \)-equivalent to

\[
SM[F_S; \text{Occurs}, \text{Occlude}] \land EQ_S
\]

where \( S \) is any subset of the set of feature symbols in \( \mathcal{N} \).

We can encode \( F_S \), for any \( S \), in the language of F2LP. However, the output of F2LP cannot be directly used with CLINGCON. This is because CLINGCON uses the special character \( \$ \) to distinguish between constraint and regular ASP atoms. So, we would need to prepend \( \$ \) to all comparison operators occurring in constraint atoms. Further, we also need to replace equality in constraint atoms with \( \$== \). For example, the constraint atoms \( f(a) + g(Y) \leq h(Z) \) and \( f(a) = X \) have to be replaced with \( f(a) + g(Y) \$\leq h(Z) \) and \( f(a) \$== X \) respectively.

Consider the “Kitchen Sink” example from the benchmark problems of the event calculus. The actions \( \text{tapOn} \) and \( \text{tapOff} \) turn the tap on and off respectively. The fluents \( \text{filling} \) and \( \text{spilling} \) represent the kitchen sink being filled and the water being spilled respectively. The fluent \( \text{waterLevel} \) represents the level of the water in the sink. Here, it is assumed that the height of the sink is 15 units and when the tap is on, the level of the water increases by 1 unit for every unit of time. Figure 9.2 shows an F2LP encoding of the example where \( \text{waterLevel} \) is used as a constraint variable. The comments (indicated by \( \% \)) show the corresponding VITAL encoding. As we can observe from the encoding, we introduced constraint
variables \texttt{waterLevel(T)} corresponding to the fluent \texttt{waterLevel}. The construct 
\texttt{#spatom{...}} used in the encoding directs F2LP to copy the part within the 
parantheses to the output without any processing. The following changes need to 
be made to the output of F2LP in order to successfully run the description with 
\texttt{CLINGCON (v. 0.1.2)}:

- since \texttt{#spatom{$domain(0..100)$}} is turned to \texttt{$domain(0..100)$ :- 
  true.}, this needs to be replaced with \texttt{$domain(0..100)$.;}

- all the comparison and equality symbols occurring in constraint atoms need 
to be replaced with the corresponding CLINGCON encoding as explained 
above; and

- since CLINGCON (v. 0.1.2) does not allow variables to begin with an 
underscore (_), every new variable \texttt{_NV_*} introduced by F2LP needs to be 
replaced with a variable not beginning with an underscore (such as \texttt{NV_*}).

The resulting program can be run using CLINGCON as follows:

\texttt{
$clingcon \ -c \ maxstep=50 \ kitchensink.lp$
}

One can verify the following from the output:

- since no action occurs until timepoint 15, the \texttt{waterLevel} is 0 and \texttt{filling} 
and \texttt{spilling} are false, for timepoints 0 to 15.

- \texttt{filling} becomes true at 16, and remains so until 45.

- starting from 17, \texttt{waterLevel} increases by 1 unit until it reaches 15 (the 
height of the sink), and remains so forever since the part about the water 
being drained out is not encoded.
- spilling becomes true at 31 when the waterLevel becomes 15, and remains so until 45.

We tested several examples with CLINGCON (v. 0.1.2), and the experimental results presented in the next section clearly show the advantages of using CLINGCON on numeric domains when compared to pure ASP solvers such as CLINGO. Since CLINGCON (v. 0.1.2) allows only integers in the domain of constraint variables, we could not test certain examples, such as the RAH scenario, which do not have any numeric domains.

9.5 Comparison with VITAL

VITAL\textsuperscript{6} is a tool for reasoning about actions using TAL. The tool supports rich features, including ramification constraints, qualification constraints, and durational fluents. It not only generates the models but also provides a visualization of the models, which makes it easier to verify the output. VITAL is essentially a research tool mainly intended for generating and visualizing the models of the descriptions. While it has some optimizations for certain types of narratives, raw performance was not a primary factor in the design and implementation of the tool.\textsuperscript{7} Nonetheless, we think it is useful to compare the performance of VITAL with that of our ASP-based approach since it would give us an idea about the performance of our approach.

For the comparison, we considered 3 scenarios: the Russian Airplane Hijack (RAH) scenario discussed earlier in the chapter, the water tank scenario whose TAL encoding is provided with VITAL, and the Zoo World scenario from \cite{Akman2004}. For the RAH scenario, we considered a few projection and planning problems. For the water tank scenario, we considered projection problems, and for the zoo world scenario, we considered projection and postdiction problems. All experiments were done on a Pentium machine with 3.06 GHz CPU and 4GB RAM running 64 bit Linux.

Figure 9.3 shows the comparison of VITAL (v. 2.999.910 alpha) with the following for the RAH and water tank scenarios:

\begin{itemize}
  \item F2LP (v 1.11) with GRINGO (v 3.0.3) + CLASP (v 2.0.2),
  \item F2LP (v 1.11) with CLINGCON (v 0.1.2) (GRINGO v 2.0.2 and CLASP v 1.1.1) for the water tank scenario, and
\end{itemize}

Figure 9.3: Comparison of VITAL with F2LP + answer set solvers

- F2LP (v 1.11) with GRINGO (v 3.0.3)+CMODELS (v 3.79) running MINISAT (v 2.0 beta).

In the figure, “max. step” indicates the maximum timepoint for which the tests were run. The times shown are in seconds, and were obtained using the `linux time` command for our ASP-based approach. The value shown is the sum of “user time” and “sys time” returned by the `time` command. The times shown in the parantheses are “(grounding time + solving time)”. For VITAL, the time shown is the one provided by the tool itself. Since there was a non-negligible variation in the time returned by VITAL for different executions of the same problem instance, we ran each problem instance 3 times and took the lowest among the times returned. If VITAL crossed the time limit on the first run, then we did not run that problem...
instance again. The cut-off time we used for the tools to terminate and return 1 model is 30 minutes. “NA” against a tool implies that that particular problem instance was either not tested with that tool or does not apply to that tool.

For the RAH scenario, the first two problems are projection problems and the next 4 are planning problems. Among the planning problems, the first two consider all actions to be of unit duration, and the next two consider actions with fixed lower and upper bounds on their durations. For the planning problems, “max. step” is also the length of a minimum plan. While VITAL does not support goal statements, planning problems can be encoded using dependency and domain constraints. The idea is to introduce fluents representing actions, and to use dependency constraints and domain constraints to represent the effects of actions and the constraints on the action occurrences respectively. Domain constraints are also used to specify the goal. While VITAL is in general not as efficient as TALplanner on planning problems, it allows us to represent domains, such as the RAH scenario, which involve ramification and qualification constraints, that are not allowed in TALplanner.

For the water tank scenario, the number in the problem name is the maximum value in the domain of the numbers considered. For instance, the number domain used for “WaterTank-proj-100” is $0..100$. The F2LP encoding of the water tank scenario is different when CLINGCON is used from when CLASP or CMODELS is used. In the F2LP encoding for CLINGCON, the fluents with numeric domains are treated as constraint variables, similar to how waterLevel was treated in the “kitchen sink” example discussed in the previous section. The last three problems in the water tank scenario correspond to the first 3 problems but they use an alternative (non-CSP) F2LP encoding where the unique value axioms

---

8This was suggested by Jonas Kvarnström in a personal communication.
9Recall that the (partial) solutions to the ramification and qualification problems use dependency constraints.

Figure 9.4: Zoo World in VITAL vs. Zoo World in F2LP + answer set solvers

are not explicitly specified. This is because, for this particular scenario, the F2LP encoding can be modified so that the value of each fluent is uniquely determined at every timepoint. As the results show, this modification has a significant impact on the times taken for GRINGO+ CLASP and GRINGO+ CMODELS to return an answer set.

Figure 9.4 shows the comparison with VITAL for the zoo world scenario.

The first two problems in this figure are projection problems, and the remaining are postdiction problems. For the postdiction problems, we gave an incomplete initial state along with certain constraints on the final state, and ran the tools to determine the complete initial state.

As we can see from the results, VITAL performed quite well on the projection problems but is not very efficient on the planning and postdiction problems we considered. On the other hand, our ASP-based approach performed equally well on all the problems, except on those involving numeric domains, such as the water tank scenario. The results also clearly show the usefulness of hybrid answer set solvers such as CLINGCON on numeric domains.
Proof of Theorem 28

Given a narrative \( \mathcal{N} \) and the corresponding preferred narrative \( \Delta_{\mathcal{N}} \), we can conclude the following:

**(ob1)** all occurrences of \( \text{Occlude} \) in \( \Gamma_{\text{acs}} \) and \( \Gamma_{\text{depc}} \) are strictly positive, and there are no strictly positive occurrences of \( \text{Occurs} \) in either of them;

**(ob2)** all occurrences of \( \text{Occurs} \) in \( \Gamma_{\text{occ}} \) are strictly positive, and there are no occurrences of \( \text{Occlude} \) in it;

**(ob3)** \( \Gamma_{\text{domc}}, \Gamma_{\text{obs}}, \Gamma_{\text{fnd}}, \) and \( \Gamma_{\text{time}} \) do not contain any occurrences of either \( \text{Occlude} \) or \( \text{Occurs} \); and

**(ob4)** all occurrences of \( \text{Occlude} \) in \( \Gamma_{\text{per}} \) are in the scope of negation, and there are no occurrences of \( \text{Occurs} \) in it.

The equivalence between (a) and (b) follows from Theorem 4, and observations (ob1) and (ob2) above which imply that \( \Gamma_{\text{occ}} \) is canonical relative to \( \text{Occurs} \) and \( \Gamma_{\text{depc}} \land \Gamma_{\text{acs}} \) is canonical relative to \( \text{Occlude} \). The equivalence between (b) and (c) follows from Theorem 12, and observations (ob1)-(ob4) above which imply that the conditions for applying the splitting theorem (Theorem 12, Chapter 4.1) are satisfied. \( \square \)

**Proof of Theorem 29**

Consider \( \Gamma_{\text{occ}} \land \Gamma_{\text{depc}} \land \Gamma_{\text{acs}} \land \Gamma_{\text{ncirc}} \), where \( \Gamma_{\text{ncirc}} \) is \( \Gamma_{\text{fnd}} \land \Gamma_{\text{time}} \land \Gamma_{\text{per}} \land \Gamma_{\text{obs}} \land \Gamma_{\text{dome}} \). The only intensional predicates in these formulas are \( \text{Occurs} \) and \( \text{Occlude} \). Among the formulas, only \( \Gamma_{\text{depc}}, \Gamma_{\text{acs}}, \) and \( \Gamma_{\text{per}} \) contain occurrences of \( \text{Occlude} \), and only \( \Gamma_{\text{acs}} \) and \( \Gamma_{\text{occ}} \) contain occurrences of
Occurs. From the definitions of an application formula and Trans, it follows that Occlude is outside the scope of any positive occurrence of ∃ and any negative occurrence of ∀ in \( \Gamma_{depc} \land \Gamma_{acs} \). Further, it is clear that all occurrences of Occlude in \( \Gamma_{per} \) are in the scope of negation, and that Occurs is outside the scope of any positive occurrence of ∃ and any negative occurrence of ∀ in \( \Gamma_{acs} \land \Gamma_{occ} \). This implies that \( \Gamma_{occ} \land \Gamma_{depc} \land \Gamma_{acs} \land \Gamma_{ncirc} \) is almost universal relative to \( \{ \text{Occurs}, \text{Occlude} \} \). The result follows from Theorem 16.

Proof of Theorem 30

Follows from Lemma 9.
Integrating nonmonotonic rules and ontologies is an important area of the semantic web research. Since the Web Ontology Language (OWL), which has been endorsed by the World Wide Web Consortium (W3C), is based on Description Logics (DLs), much of the work in this area focuses on integrating nonmonotonic rules and DLs. The knowledge base resulting from combining a DL knowledge base with nonmonotonic rules is usually referred to as a hybrid knowledge base.

A hybrid knowledge base is a pair \((T, P)\) where \(T\) is a FOL knowledge base (typically in a description logic) of signature \(\Sigma_T\) and \(P\) is a logic program of signature \(\Sigma_P\). As discussed in Chapter 2.6, the existing integration approaches can be classified into three categories: loose integration, tight integration with semantic separation, and tight integration under a unifying logic (Nazarenko et al., 2010). In the loose integration approach, \(T\) and \(P\) are viewed as separate, independent components, and are connected through minimal safe interfaces for exchanging data (usually in the form of ground atoms). Examples in this category include nonmonotonic dl-programs (Eiter et al., 2008), and the combination of description logics and defeasible logic (Wang et al., 2004). In the tight integration with semantic separation approach, \(T\) and \(P\) are more tightly integrated, but the predicates in \(\Sigma_T\) and \(\Sigma_P\) are kept separate. This approach builds an integrated model \(I\) as the union of a model \(I_T\) of \(T\) and a model \(I_P\) of \(P\) with the same domain. Examples in this category are \(r\)-hybrid KB (Rosati, 2005), \(DL + log\) (Rosati, 2006), \(g\)-hybrid KB (Heymans et al., 2008), and \(f\)-hybrid KB (Feier & Heymans, 2009). Finally, in the tight integration under a unifying logic approach, \(T\) and \(P\) are treated uniformly by translating them into a uniform logic, and there is no principled separation between \(\Sigma_T\) and \(\Sigma_P\). Examples in this category are
Hybrid MKNF KB (Motik & Rosati, 2010), the first-order Autoepistemic Logic based integration (de Bruijn et al., 2007a), and the Quantified Equilibrium Logic based integration (de Bruijn et al., 2007b). This approach is attractive since it provides a seamless integration of DLs and logic programs, and since the information flow is bi-directional.

In this chapter, we use the framework of the first-order stable model semantics to integrate Description Logics (DLs) and ASP. We show how our approach can capture several approaches belonging to each of the categories discussed above. We also show how the research on the first-order stable model semantics can be used to strengthen certain decidability results for $\mathcal{DL} + \mathit{log}$ (Rosati, 2006) and to define the notion of strong equivalence (Chapter 3.2) for hybrid knowledge bases. Several parts of this chapter are also presented in (Lee & Palla, 2011a, 2011b).

10.1 Integrating Description Logic Knowledge Bases and Answer Set Programming Rules

DL knowledge bases can be viewed as theories in first-order logic. Since the first-order stable model semantics generalizes both ASP and first-order logic, it provides an ideal framework for integrating ASP-rules and DL knowledge bases. Given a DL knowledge base $\mathcal{T}$ of signature $\Sigma_T$ and a logic program $\mathcal{P}$ of signature $\Sigma_P$, our approach is to identify the models of the hybrid knowledge base $(\mathcal{T}, \mathcal{P})$ with the interpretations of signature $\Sigma_T \cup \Sigma_P$ (in the sense of classical logic) that satisfy $\mathit{SM}[\mathit{FO}(\mathcal{T}) \land \mathit{FO}(\mathcal{P}); \mathbf{p}]$, where $\mathit{FO}(\mathcal{T})$ and $\mathit{FO}(\mathcal{P})$ are the first-order representations of $\mathcal{T}$ and $\mathcal{P}$ respectively, and $\mathbf{p}$ is a list of intensional predicates. We assume that $\mathcal{T}$ and $\mathcal{P}$ are finite, and so are the predicate constants in $\Sigma_P$. Typically, existing integration approaches assume that the signatures do not contain function constants of positive arity, and $\Sigma_T$ and $\Sigma_P$ share the same set of object constants, but have disjoint sets of predicate constants.
Note here that we do not place any restriction on the syntax of $\mathcal{P}$ or on the signatures of $\mathcal{T}$ and $\mathcal{P}$. Further, the interpretations considered are first-order interpretations. This shows that both $\mathcal{T}$ and $\mathcal{P}$ are treated uniformly, which in turn indicates that our approach is faithful and tight. The intensional predicates are usually the predicate constants in $\Sigma_\mathcal{P}$ that do not belong to $\Sigma_\mathcal{T}$. However, the list of intensional predicates can be increased or decreased as necessary. Since both $\mathcal{T}$ and $\mathcal{P}$ are viewed uniformly under the first-order stable model semantics, our approach belongs to the tight integration under a unifying logic category discussed above.

**Example 12** (de Bruijn et al., 2007b, Example 1) Consider a hybrid knowledge base consisting of a classical theory $\mathcal{T}$:

\[
\forall x (Person(x) \rightarrow (Agent(x) \land (\exists y HasMother(x, y)))) \\
\forall x ((\exists y HasMother(x, y)) \rightarrow Animal(x))
\]

which says that every Person is an Agent and has some (unknown) mother, and everyone who has a mother is an Animal, and a nonmonotonic logic program $\mathcal{P}$:

Person($x$) ← Agent($x$), not machine($x$)

Agent(DaveB)

which says that Agents are by default Persons, unless known to be machines, and DaveB is an Agent. The predicate constants starting in capital letters belong to $\Sigma_\mathcal{T}$, and the rest of the predicate constants belong to $\Sigma_\mathcal{P} \setminus \Sigma_\mathcal{T}$. It follows that $SM[FO(\mathcal{T}) \land FO(\mathcal{P}) ; machine]$ entails Person(DaveB), $\exists y HasMother(DaveB, y)$, and Animal(DaveB).

Since we do not place any restrictions on the syntax of the logic programs, we can even use quantifiers if necessary. Sometimes, quantifiers also enable succinct representation.
Example 13 Consider a hybrid knowledge base where $T$ is
\begin{align*}
\forall x (\text{Student}(x) \rightarrow \text{Person}(x)) \\
\forall x (\text{Professor}(x) \rightarrow \text{Person}(x)) \\
\forall x (\text{Professor}(x) \rightarrow \exists y (\text{Teaches}(x, y) \land \text{Course}(y))) \\
\forall x (\text{unregistered}(x) \rightarrow \text{Professor}(x)) \\
\forall x (\exists y (\text{registered}(x, y) \land \text{Course}(y)) \rightarrow \text{Student}(x)) \\
\text{Course}(A) \\
\text{Course}(B)
\end{align*}
and $P$ is
\begin{align*}
\text{unregistered}(x) & \leftarrow \text{not } \exists y (\text{registered}(x, y) \land \text{Course}(y)) \land \text{Person}(x) \\
\text{registered}(\text{Joe}, A) \\
\text{Person}(\text{Mary}).
\end{align*}

It is not difficult to verify that $SM[\text{FO}(T) \land \text{FO}(P); \text{registered}, \text{unregistered}]$ entails $\text{Professor}(\text{Mary}), \exists y (\text{Teaches}(\text{Mary}, y) \land \text{Course}(y)), \text{Student}(\text{Joe}), \text{Person}(\text{Joe}), \text{and } \neg \exists xy (\text{registered}(x, y) \land \text{unregistered}(x))$.

10.2 Relation to $\mathcal{DL} + \log$

In $\mathcal{DL} + \log$, predicate constants are partitioned into DL predicates $P_T$ and Datalog predicates $P_P$. DL predicates are further partitioned into concept names and role names. Additionally, $\mathcal{DL} + \log$ assumes a countably infinite set of object constants, denoted by $C$.

A $\mathcal{DL} + \log$ knowledge base is denoted by $(T, P)$, where $T$ is a DL knowledge base of signature $\langle C, P_T \rangle$ and $P$ is a Datalog program of signature $\langle C, P_T \cup P_P \rangle$ consisting of rules $R$ of the form
\begin{equation}
\begin{array}{l}
p_1(X_1); \ldots; p_n(X_n) \leftarrow \\
r_1(Y_1), \ldots, r_m(Y_m), s_1(Z_1), \ldots, s_k(Z_k), \\
\text{not } u_1(W_1), \ldots, \text{not } u_h(W_h)
\end{array}
\end{equation}
(n ≥ 0, m ≥ 0, k ≥ 0, h ≥ 0) where \(X_i, Y_i, Z_i, W_i\) are lists of object variables and object constants, and

- each \(p_i\) is either a DL predicate or a Datalog predicate;
- each \(r_i, u_i\) is a Datalog predicate;
- each \(s_i\) is a DL predicate;
- (Datalog safety) every variable occurring in \(R\) must also occur in at least one of the atoms \(r_1(Y_1), \ldots, r_m(Y_m), s_1(Z_1), \ldots, s_k(Z_k)\); 
- (Weak safety) every variable occurring in the head of \(R\) must also occur in at least one of the atoms \(r_1(Y_1), \ldots, r_m(Y_m)\).

Rosati (2006) presents two semantics of \(\mathcal{DL} + \log\) KB: the monotonic and the nonmonotonic semantics. The monotonic semantics of \(\mathcal{DL} + \log\) is given by simply viewing \(\mathcal{T}\) and \(\mathcal{P}\) as theories in first-order logic: given a \(\mathcal{DL} + \log\) knowledge base \((\mathcal{T}, \mathcal{P})\) of signature \(\langle C, P_T \cup P_P \rangle\), an interpretation \(I\) is a monotonic model of \((\mathcal{T}, \mathcal{P})\) if \(I\) satisfies \(\text{FO}(\mathcal{T}) \land \text{FO}(\mathcal{P})\). Since a first order theory can be characterized in the first-order stable model semantics by making the list of intensional predicates empty, the monotonic semantics of \(\mathcal{DL} + \log\) can be expressed by \(\text{SM}[\text{FO}(\mathcal{T}) \land \text{FO}(\mathcal{P}); \emptyset]\).

The nonmonotonic semantics of \(\mathcal{DL} + \log\) is based on the stable model semantics for disjunctive logic programs. The notation \(\text{gr}(\mathcal{P}, C)\) represents the ground program obtained by replacing every variable in every rule of \(\mathcal{P}\) with every object constant in \(C\).

Given \(\text{gr}(\mathcal{P}, C)\) and an interpretation \(I\) of signature \(\langle C, P_T \rangle\), the projection of \(\text{gr}(\mathcal{P}, C)\) with respect to \(I\), denoted by \(\Pi(\text{gr}(\mathcal{P}, C), I)\), is obtained as follows. For every rule \(R \in \text{gr}(\mathcal{P}, C)\),
• delete $R$ if $I \models r(t)$ for some head atom $r(t)$ such that $r \in P_T$;

• delete every atom $r(t)$ in the head such that $r \in P_T$ and $I \not\models r(t)$;

• delete $R$ if $I \not\models r(t)$ for some atom $r(t)$ in the body such that $r \in P_T$;

• delete every atom $r(t)$ in the body such that $r \in P_T$ and $I \models r(t)$.

The $\mathcal{DL} + \log$ approach imposes the standard name assumption: every interpretation is over the same fixed, countably infinite, domain $\Delta$, and in addition, the set $C$ of object constants is such that it is in the same one-to-one correspondence with $\Delta$ in every interpretation. As a result, for simplicity, we assume that the domain with respect to every interpretation is $C$.

An interpretation $I$ (in the sense of classical logic) of a signature $\sigma$ can be represented as a pair $\langle I^f, X \rangle$, where $I^f$ is the restriction of $I$ to function constants (including object constants) from $\sigma$, and $X$ is the set of atoms, formed using predicate constants from $\sigma$ and the names of elements of $|I|$, which are satisfied by $I$.

Given a $\mathcal{DL} + \log$ knowledge base $(T, P)$ of signature $\langle C, P_T \cup P_P \rangle$, an interpretation $I$ is a nonmonotonic model of $(T, P)$ if

• $I|_C$ (the restriction of $I$ on $C$) is an identity function that maps every constant in $C$ to itself;

• $\langle I|_C, I|_{P_T} \rangle$ satisfies $T$;

• $\langle I|_C, I|_{P_T} \rangle$, identified with a set of ground atoms, is an answer set of $\Pi(gr(P, C), \langle I|_C, I|_{P_T} \rangle)$.

The following proposition shows how the nonmonotonic semantics of $\mathcal{DL} + \log$ can be reformulated in terms of the first-order stable model semantics.
Theorem 31  For any $\mathcal{DL} + \log$ knowledge base $(\mathcal{T}, \mathcal{P})$, under the standard name assumption, the nonmonotonic models of $(\mathcal{T}, \mathcal{P})$ according to (Rosati, 2006) are precisely the interpretations of $(\mathcal{C}, P_T \cup P_P)$ that satisfy

$$SM[FO(\mathcal{T}) \land FO(\mathcal{P}); P_P].$$

Since the reformulation does not refer to grounding, arguably, it provides a simpler account of $\mathcal{DL} + \log$.

**Discarding Datalog Safety**

$\mathcal{DL} + \log$ imposes weak safety (every variable occurring in the head of a rule also occurs in a Datalog atom in the positive body) and Datalog safety (every variable occurring in a rule also occurs in the positive body), which, even when combined, yields a condition that is weaker than DL-safety (Motik, Sattler, & Studer, 2005), where every variable occurring in a rule is also required to occur in a datalog atom in the positive body. Here, we use the concept of semi-safety discussed in Chapters 6.1 and 6.3 to show that the assumption of weak safety is a sufficient condition for guaranteeing decidability of reasoning with $\mathcal{DL} + \log$.

First, we slightly generalize the definition of semi-safety to the case where the list of intensional predicates can be arbitrary. We start with generalizing the definition of $RV(F)$ (restricted variables of $F$) to differentiate between intensional and extensional predicates. As before, we assume that the signature contains no function constants of positive arity. To every quantifier-free formula $F$, we assign a set $RV_p(F)$ of restricted variables relative to $p$ as follows.

- For an atomic formula $F$ (including equality and $\bot$),
  - if $F$ is an equality between two variables, or is an atom whose predicate constant is not in $p$, then $RV_p(F) = \emptyset$;
  - otherwise, $RV_p(F)$ is the set of all variables occurring in $F$;
We say that a variable \( x \) is \( p \)-restricted in a quantifier-free formula \( F \) if \( x \in RV_p(F) \).

Recall that an occurrence of a predicate constant, a variable, or any other subexpression in a formula \( F \) is \textit{strictly positive} if that occurrence is not in the antecedent of any implication.

Consider a sentence \( F \) in prenex form:

\[
Q_1x_1 \cdots Q_nx_n M
\]

(\( Q_i \) is \( \forall \) or \( \exists \); \( x_1, \ldots, x_n \) are distinct variables; the matrix \( M \) is quantifier-free).

We say that \( F \) is \textit{semi-safe relative to} \( p \) if every strictly positive occurrence of every variable \( x_i \) in \( M \) belongs to a subformula \( G \rightarrow H \) where \( x_i \) is \( p \)-restricted in \( G \).

The \textit{small predicate property} (Chapter 6.1) is generalized as follows. A \( p \)-stable model of \( F \) has the \textit{small predicate property} if, for every predicate constant \( p_i \in p \), if the relation represented by it holds for a tuple of arguments, then each member of the tuple is represented by an object constant occurring in \( F \). As before, the idea can be made precise as follows. For any finite set \( c \) of object constants, \( in_c(x) \) stands for the formula

\[
\bigvee_{c \in c} x = c.
\]

The \textit{small predicate property relative to} \( p \), denoted by \( SPP^p_c \), is the conjunction of the sentences

\[
\forall v_1, \ldots, v_n \left( p(v_1, \ldots, v_n) \rightarrow \bigwedge_{i=1, \ldots, n} in_c(v_i) \right)
\]

for all predicate constants \( p \) in \( p \), where \( v_1, \ldots, v_n \) are distinct variables.
The following proposition is an extension of Proposition 3 in Chapter 6.1.\footnote{This extension is presented in (Bartholomew & Lee, 2010).}

By $c(F)$ we denote the set of all object constants occurring in $F$.

**Proposition 5** For any semi-safe sentence $F$ relative to $p$, formula $SM[F; p]$ entails $SPP_{c(F)}^p$.

Now, we will show how this proposition can be used to drop the condition of datalog safety in $\mathcal{DL} + log$. Since we identify Datalog predicates with intensional predicates, and DL predicates with non-intensional predicates, the definition of semi-safety presented above coincides with the definition of weak-safety for programs whose rules have the form (10.1). Therefore, from Proposition 5 and Theorem 31, we get that the relations represented by the datalog predicates can hold for a tuple of arguments only if each member of the tuple is a constant occurring in the program $P$. Since the universe is a countably infinite set of constants $C$, it follows that if a literal in a rule (10.1) contains a variable that occurs only in the negative body, then that literal can be simply replaced with $\top$. The following theorem makes this precise.

**Theorem 32** Let $\mathcal{K} = (T, P)$ be a $\mathcal{DL} + log$ knowledge base such that $P$ is weakly safe but is not necessarily datalog safe. Let $P'$ be the program obtained from $P$ by removing in every rule, all the negative datalog literals that contain a variable that occurs only in the negative body. Then $\mathcal{K}$ is equivalent (under the nonmonotonic semantics) to the $\mathcal{DL} + log$ knowledge base $(T, P')$.

Since the complexity of the transformation required to obtain $P'$ is polynomial in the size of $P$, the decidability results (Theorems 11 and 12 from (Rosati, 2006)) and the complexity results (Theorem 13 from (Rosati, 2006)) with respect to the nonmonotonic semantics can be straightforwardly carried over...
to $\mathcal{DL} + \log$ knowledge bases $(T, \mathcal{P})$ where $\mathcal{P}$ is weakly safe but not necessarily datalog safe. In other words, in terms of decidability and complexity results mentioned above, the requirement of datalog safety can be dropped.

10.3 Relation to Quantified Equilibrium Logic with Hybrid Rules

Review of Quantified Equilibrium Logic

Quantified Equilibrium Logic (QEL) (Pearce & Valverde, 2005) is based on the Quantified Here-and-There Logic (QHT). Here we will review QHT and QEL without function constants and strong negation as presented in (de Bruijn et al., 2007b). Consider a function-free signature $\Sigma$ consisting of a set of object constants $C$ and a set of predicate constants $P$. A here-and-there $\Sigma$-structure with static domains ($\text{QHT}^s(\Sigma)$-structure) is a tuple $M = \langle (D, \sigma), I_h, I_t \rangle$ where

- $D$ is a non-empty set, called the domain of $M$,
- $\sigma$ is a mapping $C \cup D \rightarrow D$ such that $\sigma(d) = d$ for all $d \in D$,
- $I_h$ and $I_t$ are interpretations of $\Sigma$ over $D$ such that for every $p^h \subseteq p^t$ for all $p \in P$.

Here $M$ can be seen as a first-order model having two components, $h$ and $t$, that correspond to the “here” world and “there” world respectively in the sense of Kripke semantics for intuitionistic logic (van Dalen, 1983), such that whatever is verified in $h$ remains true at $t$. For any sentence $F$, $M, w \models F$, where $w = \{h, t\}$, is defined as follows:

- $M, w \models p(t_1, \ldots, t_n)$ iff $(\sigma(t_1), \ldots, \sigma(t_n)) \in p^w$,
- $M, w \models G \land H$ iff $M, w \models G$ and $M, w \models H$,
- $M, w \models G \lor H$ iff $M, w \models G$ or $M, w \models H$,
- $M, t \models G \rightarrow H$ iff $M, t \not\models G$ or $M, t \models H$,
\[ M, h \models G \rightarrow H \text{ iff } M, t \models G \rightarrow H \text{ and } M, h \not\models G \text{ or } M, h \models H, \]
\[ M, t \models \forall xG(x) \text{ iff } M, t \models G(d) \text{ for all } d \in D, \]
\[ M, h \models \forall xG(x) \text{ iff } M, t \models \forall xG(x) \text{ and } M, h \models G(d) \text{ for all } d \in D, \]
\[ M, w \models \exists G(x) \text{ iff } M, w \models G(d) \text{ for some } d \in D. \]

The truth of a sentence \( F \) in a model \( M \) is defined as follows: \( M \models F \text{ iff } M, w \models F \text{ for each } w \in \{ h, t \} \). The resulting logic is called the **Quantified Here-and-There Logic with static domains**.

In order to define QEL, the notion of a “minimal” model is needed. Among two QHTs \( (\Sigma) \) structures \( \langle (D, \sigma), I_h, I_t \rangle \) and \( \langle (D', \sigma'), I'_h, I'_t \rangle \),
\[ \langle (D, \sigma), I_h, I_t \rangle \preceq \langle (D', \sigma'), I'_h, I'_t \rangle \text{ if } D = D', \sigma = \sigma', I_t \text{ agrees with } I'_t \text{ on } \Sigma, \text{ and } \]
\[ p^{I_h} \subseteq p^{I'_h} \text{ for all } p \in P. \]
A model \( M = \langle (D, \sigma), I_h, I_t \rangle \) of \( F \) is total if \( I_h \) agrees with \( I_t \) on \( \Sigma \). \( M \) is an **equilibrium model** of \( F \) if it is minimal under \( \preceq \) among models of \( F \), and it is total.

**Relation to the Quantified Equilibrium Logic Based Approach**

Recall that \( \text{Choice}(p) \) denotes the conjunction of “choice formulas”
\[ \forall x(p(x) \lor \neg p(x)) \] for all predicate constants \( p \) in \( p \) where \( x \) is a list of distinct object variables whose length is the same as the arity of \( p \). The approach in (de Bruijn et al., 2007b) uses QEL to integrate rules and ontologies. According to that approach, a QHT\( ^s(\langle C, P_T \cup P_P \rangle) \) interpretation is a model of the hybrid knowledge base \( \mathcal{K} = (T, P) \) iff it is an equilibrium model of \( FO(T) \land FO(P) \land \text{Choice}(P_T) \).

Formula \( FO(T) \land FO(P) \land \text{Choice}(P_T) \) is called the **stable closure** of \( \mathcal{K} \). The following proposition shows the relationship between the QEL-based approach and our approach.

**Proposition 6** For any hybrid knowledge base \( \mathcal{K} = (T, P) \) of signature
\[ \langle C, P_T \cup P_P \rangle, \] a QHT\( ^s(\langle C, P_T \cup P_P \rangle) \) interpretation \( I = \langle (D, \sigma), I_t, I_t \rangle \) is an
equilibrium model of K in the sense of (de Bruijn et al., 2007b) iff \( \langle I_C, I_{P_T \cup P_P} \rangle \) satisfies

\[
SM[FO(T) \land FO(P); P_P].
\]

The proof of the proposition is immediate from Lemma 9 from (Ferraris et al., 2011), which establishes the relationship between QEL and \( SM[F; p] \) for the special case when \( p \) is the list of all predicate constants in the signature, and Proposition 1, which tells us that the set of intensional predicates can be increased by using choice formulas.

10.4 Relation to \( g \)-hybrid Knowledge Bases

de Bruijn et al. (2007b) relate the QEL-based approach to \( r \)-hybrid (Rosati, 2005) and \( g \)-hybrid knowledge bases (Heymans et al., 2008). As a corollary of Proposition 6 in this paper, we can thus relate our approach to \( r \)-hybrid and \( g \)-hybrid knowledge bases. Here we present the result only with respect to \( g \)-hybrid knowledge bases since we already covered the relationship to \( DL^+ \log \), which is an extension of \( r \)-hybrid knowledge bases.

\( g \)-hybrid knowledge bases are based on the open answer set programming (Heymans, Nieuwenborgh, & Vermeir, 2005) approach. More specifically, a \( g \)-hybrid knowledge base is a pair \( (T, P) \), where \( T \) is a DL knowledge base of signature \( \langle C, P_T \rangle \) and \( P \) is a guarded program of signature \( \langle C, P_T \cup P_P \rangle \) such that \( P_T \cap P_P = \emptyset \). A program is said to be guarded if, for all rules \( R \) that are not of the form

\[
p(t) \lor \text{not } p(t) \leftarrow ,
\]

there exists an atom \( A \) in the positive body (known as the guard) such that all the variables occurring in \( R \) also occur in \( A \). This implies that, in addition to such safe rules \( R \), guarded programs also allow unsafe choice rules of the form (10.3). Also,
guarded programs allow negation in the head but with the restriction that there can be at most one non-negated atom in the head.

Given an interpretation $I$ of signature $\langle C, P_T \cup P_P \rangle$, program $P_I$ is defined as the ground program obtained from $P$ by first replacing every occurrence of $c$ from $C$ in it with $c_I$ and then grounding the resulting program with respect to the universe of $I$. Interpretation $I$ is a model of the $g$-hybrid knowledge base $(T, P)$ if

- the restriction of $I$ to $\langle C, P_T \rangle$ is a model of $T$, and
- the restriction of $I$ to $\langle C, P_P \rangle$, viewed as a set of ground atoms, is an answer set of $\Pi(P_I, I)$.

The following proposition is a corollary of Theorem 2 from (de Bruijn et al., 2007b) and Proposition 6.

**Proposition 7** For any $g$-hybrid knowledge base $K = (T, P)$, an interpretation $I$ of signature $\langle C, P_T \cup P_P \rangle$ is a model of $K$ in the sense of (de Bruijn et al., 2007b) iff $I$ is a model of

$$SM[FO(T) \land FO(P); P_P].$$

10.5 Relating to Nonmonotonic dl-programs

Review of Nonmonotonic dl-programs

We first review the syntax and the semantics of dl-programs. For simplicity, we do not allow strong negation. A nonmonotonic dl-program (Eiter et al., 2008) is a pair $(T, P)$, where $T$ is a DL knowledge base of signature $\langle C, P_T \rangle$ and $P$ is a generalized normal logic program of signature $\langle C, P_P \rangle$ such that $P_T \cap P_P = \emptyset$. A generalized normal logic program is a set of dl-rules that can contain queries to $T$ in their bodies, in the form of dl-atoms.

---

2The definition of projection $\Pi$ given earlier is straightforwardly extended to cover a rule like (10.3) that allows not in the head.
A *dl-atom* is of the form

\[
DL[S_1 op_1 p_1, \ldots, S_m op_m p_m; \ Q](t) \quad (m \geq 0)
\]

(10.4)

where each \( S_i \) is a concept, a role or a special symbol \( \theta \in \{=, \neq \} \), symbol \( p_i \) is a unary predicate constant if \( S_i \) is a concept and a binary predicate constant otherwise and \( op_i \in \{\oplus, \odot, \ominus\} \); \( Q(t) \) is a dl-query (Eiter et al., 2008).

A *dl-rule* is of the form

\[
a \leftarrow b_1, \ldots, b_k, \ not \ b_{k+1}, \ldots, not \ b_m
\]

(10.5)

where \( a \) is an atom and each \( b_i \) is either an atom, equality, or a dl-atom. We identify rule (10.5) with

\[
a \leftarrow B, N
\]

(10.6)

where \( B \) is \( b_1, \ldots, b_k \) and \( N \) is \( not \ b_{k+1}, \ldots, not \ b_m \).

The semantics of dl-programs is defined by extending the answer set semantics to generalized programs. In order to do this, the definition of satisfaction is extended to ground dl-atoms. An Herbrand interpretation \( I \) satisfies a ground atom \( A \) relative to \( T \) if \( I \) satisfies \( A \). An Herbrand interpretation \( I \) satisfies a ground dl-atom (10.4) relative to \( T \) if \( T \cup \bigcup_{i=1}^{m} A_i(I) \) entails \( Q(t) \), where \( A_i(I) \) is

- \( \{ S_i(e) \mid p_i(e) \in I \} \) if \( op_i \) is \( \oplus \),
- \( \{ \neg S_i(e) \mid p_i(e) \in I \} \) if \( op_i \) is \( \odot \),
- \( \{ \neg S_i(e) \mid p_i(e) \notin I \} \) if \( op_i \) is \( \ominus \),

and \( t \) is any list of ground terms. The satisfaction relation is extended to allow connectives in the usual way.

Given a dl-program \((T, P)\), the *weak dl-transform* of \( P \) relative to \( T \) and an Herbrand interpretation \( I \) of \( \langle C, P_P \rangle \), denoted by \( w P_T^I \), is the logic program obtained from \( gr(P, C) \) by deleting
• each rule (10.6) in \( gr(P, C) \) such that
  
  – \( I \not\models_T b \) for some dl-atom \( b \) in \( B \), or
  
  – \( I \models_T b \) for some literal \( \text{not} \ b \) in \( N \);

• from each remaining dl-rule (10.6), all the dl-atoms in \( B \) and all the literals in \( N \).

\( I \) is a weak answer set of \((T, P)\) if \( I \) is the minimal model of \( wP^I_T \).

By \( DL^3_P \) we denote the set of dl-atoms in \( gr(P, C) \) that are not known to be monotonic. The strong dl-transform of \( P \) relative to \( T \) and \( I \), denoted by \( sP^I_T \), is the logic program obtained from \( gr(P, C) \) by deleting

• each rule (10.6) in \( gr(P, C) \) such that
  
  – \( I \not\models_T b \) for some dl-atom \( b \) in \( B \cap DL^3_P \) or
  
  – \( I \models_T b \) for some not \( b \) in \( N \);

• from each remaining dl-rule (10.6), all the dl-atoms in \( B \cap DL^3_P \) and all the literals in \( N \).

\( I \) is a strong answer set of \((T, P)\) if \( I \) is the minimal model of \( sP^I_T \).

Relation to Nonmonotonic dl-programs

In order to relate our approach to the semantics of dl-programs, we define
dl-formulas of signature \( \langle C, P_T \cup P_T \rangle \) as an extension of first-order formulas by treating dl-atoms as a base case in addition to standard atomic formulas formed from \( \langle C, P_T \rangle \).\(^3\) Note that any generalized normal logic program can be viewed as a dl-formula: \( FO(P) \) can be extended to a generalized normal logic program \( P \) in a

\(^3\)The extension is similar to the extension of first-order formulas to allow aggregate expressions as given in (Lee & Meng, 2009).
straightforward way. Let \( F \) be a variable-free dl-formula.\(^4\) We define \( F^w* \) the same as \( F^* \) except for a new clause for a dl-atom:

\[
DL[S_1op_1p_1, \ldots, S_mop_mp_m; Q](\mathbf{c})^w*(\mathbf{u}) = DL[S_1op_1p_1, \ldots, S_mop_mp_m; Q](\mathbf{c}).
\]

\( SM^w[F] \) is defined the same as formula \( SM[F] \) except that \( F^w* \) is used in place of \( F^* \). The following theorem shows how weak answer sets can be characterized by this extension.

**Theorem 33** For any dl-program \((T, \mathcal{P})\) such that \( \mathcal{P} \) is variable-free, the weak answer sets of \((T, \mathcal{P})\) are precisely the Herbrand interpretations of signature \( \langle C, \mathcal{P}_p \rangle \) that satisfy \( SM^w[FO(\mathcal{P}); \mathcal{P}_p] \) relative to \( T \).

In order to capture strong answer sets, we define \( F^{s*} \) the same as \( F^* \) except for a new clause for a dl-atom:

\[
DL[S_1op_1p_1, \ldots, S_mop_mp_m; Q](\mathbf{c})^{s*}(\mathbf{u}) = DL[S_1op_1u_1, \ldots, S_mop_mu_m; Q](\mathbf{c})
\]

(u_1, \ldots, u_m are the elements of \( \mathbf{u} \) that correspond to \( p_1, \ldots, p_m \)) if the dl-atom is monotonic; otherwise

\[
DL[S_1op_1p_1, \ldots, S_mop_mp_m; Q](\mathbf{c})^{s*}(\mathbf{u}) = DL[S_1op_1p_1, \ldots, S_mop_mp_m; Q](\mathbf{c}).
\]

\( SM^s[F] \) is defined the same as \( SM[F] \) except that \( F^{s*} \) is used in place of \( F^* \). The following theorem shows how strong answer sets can be characterized by this extension.

**Theorem 34** For any dl-program \((T, \mathcal{P})\) such that \( \mathcal{P} \) is variable-free, the strong answer sets of \((T, \mathcal{P})\) are precisely the Herbrand interpretations of signature \( \langle C, \mathcal{P}_p \rangle \) that satisfy \( SM^s[FO(\mathcal{P}); \mathcal{P}_p] \) relative to \( T \).

\(^4\)We require \( F \) to be variable-free because strong answer set semantics distinguishes if a ground dl-atom is monotonic or nonmonotonic.
Above, we presented two extensions of $F^*$ to cover weak and strong semantics respectively. Further, the relationship was shown only for variable-free dl-programs. Below, we show how strong and weak semantics can be captured with a single extension of $F^*$, which also applies to dl-formulas with variables and does not differentiate between monotonic and nonmonotonic dl-atoms. The tradeoff is that the strong semantics can be captured only under certain conditions.

Consider any dl-formula $F$. We define $F^v$ by adding the following clause to the definition of $F^*$:

$$DL[S_1\text{op}_1p_1,\ldots,S_m\text{op}_mp_m;Q](t)^*(u) =$$

$$DL[S_1\text{op}_1p_1',\ldots,S_m\text{op}_mp_m';Q](t)\land$$

$$DL[S_1\text{op}_1p_1,\ldots,S_m\text{op}_mp_m;Q](t)$$

where symbol $p_i'$ is $u_i$ if $p_i$ is intensional and $p_i$ otherwise. Further, we define $SM_v[F]$ the same as $SM[F]$ except that $F^v$ is used in place of $F^*$. 

The following theorem shows how strong answer sets can be characterized by this extension of $SM$.

**Theorem 35** For any dl-program $(T,P)$ such that every occurrence of $\ominus$ is in the scope of negation, the strong answer sets of $(T,P)$ are precisely the Herbrand interpretations of $\langle C,P_P \rangle$ that satisfy $SM^v[FO(P); P_P]$ relative to $T$.

The syntactic condition about $\ominus$ in Theorem 35 ensures that all dl-atoms in the positive bodies of the ground program are monotonic. The statement does not hold if the condition is dropped. For example, consider the dl-program $(T,P)$ where the axioms in $T$ (written as first-order formulas) are

$$Q(b),$$

$$\forall x (\neg S(x) \rightarrow Q(x))$$

and $P$ is

$$p(x) \leftarrow DL[S \ominus p; Q](x).$$
For $C = \{a, b\}$, $DL[S \odot p; Q](b)$ is monotonic but $DL[S \odot p; Q](a)$ is not. One can check that $(T, \mathcal{P})$ has no strong answer sets, but $\{p(a), p(b)\}$ is an Herbrand model of $SM^*[FO(\mathcal{P}); p]$.

In the case of weak answer set semantics, the condition is not required, but instead we need to prepend $\neg\neg$ to all dl-atoms.

**Theorem 36** For any dl-program $(T, \mathcal{P})$, the weak answer sets of $(T, \mathcal{P})$ are precisely the Herbrand interpretations of signature $\langle C, P \rangle$ that satisfy $SM^*[FO(\mathcal{P})\neg; P]$, relative to $T$, where $FO(\mathcal{P})\neg$ is obtained from $FO(\mathcal{P})$ by prepending $\neg\neg$ to all occurrences of dl-atoms.

### 10.6 Strong Equivalence of Hybrid Knowledge Bases

Given two classically equivalent theories $F$ and $G$ of the same signature, and a theory $H$ containing $F$, replacing $F$ in the theory with $G$ will not change the models of $H$. However, this property does not hold in general for answer set programs, and as a result, it also does not hold in general for hybrid knowledge bases. For instance, consider a hybrid knowledge base where $T$ is empty and $\mathcal{P}$ consists of the following rules:

- $p$
- $p \leftarrow p$.

$SM[FO(T) \land FO(\mathcal{P}); p]$ is consistent. Let $\mathcal{P}'$ be the theory obtained from $\mathcal{P}$ by replacing the second rule with $\bot \leftarrow p$. Even though $p \leftarrow p$ and $\bot \leftarrow p$ have the same stable models, $SM[FO(T) \land FO(\mathcal{P}'); p]$ is inconsistent.

The notion of strong equivalence (Ferraris et al., 2011), reviewed in Chapter 3.2, ensures that the stable models of a formula $F$ do not change if a subformula $G$ is replaced with a formula that strongly equivalent to $G$. Similar to (de Bruijn et al., 2007b), we carry over this notion to hybrid knowledge bases.
We say that two hybrid knowledge bases \((T_1, P_1)\) and \((T_2, P_2)\) of the same signature \(\Sigma_T \cup \Sigma_P\) are strongly equivalent if the formula

\[
u \leq pr(\Sigma_P \setminus \Sigma_T) \rightarrow \left( (FO(T_1) \land FO(P_1))^*(\nu) \leftrightarrow (FO(T_2) \land FO(P_2))^*(\nu) \right)
\]

is logically valid where \(pr(\Sigma_P \setminus \Sigma_T)\) is the set of all predicates constants in \(\Sigma_P\) that do not belong to \(\Sigma_T\).

### 10.7 Related Work

Like our extension, the QEL-based approach (de Bruijn et al., 2007b) was extended to cover dl-programs in (Fink & Pearce, 2010). In that paper, the authors capture the weak (strong, respectively) semantics of dl-programs by defining weak (strong, respectively) QHT models of dl-atoms. The extensions \(F_w^*\) and \(F_s^*\) of \(F^*\) we presented above are syntactic counterparts of these definitions of QHT models. In (de Bruijn, Pearce, Polleres, & Valverde, 2010), the authors slightly modify the definition of \(SM\) and show how the modified definition can be used to integrate rules and ontologies.

Motik and Rosati (2010) present an unification of DL knowledge bases and logic programs in the framework of the logic of Minimal Knowledge and Negation as Failure (MKNF) (Lifschitz, 1991). They also show how their framework captures several of the existing integration approaches. In order to capture the semantics of dl-programs, they unfold dl-atoms into MKNF formulas. For instance,

\[
DL[Q \oplus p; R](a)
\]

is unfolded into the formula (Motik & Rosati, 2010, Definition 7.5)

\[
K\left( (FO(T) \land \forall x(p(x) \rightarrow Q(x)) \rightarrow R(a) \right)
\]

where \(T\) is the DL knowledge base. Such an unfolding does not work with our semantics. For example, consider \(K = (T, P)\) such that \(T\) is empty, and \(P\) is the
following:

\[
p(a) \leftarrow DL[Q \oplus p; R](a) \\
\leftarrow \text{not } p(a).
\]  

(10.7)

Since \(DL[Q \oplus p; R](a)\) cannot be satisfied by any set of atoms formed using \((a, p/1)\), \(P\) has neither strong nor weak answer sets. On the other hand, if we represent \(DL[Q \oplus p; R](a)\) by

\[
(\forall x(p(x) \rightarrow Q(x))) \rightarrow R(a),
\]

the FOL-representation of (10.7) is

\[
F = \left( (\forall x(p(x) \rightarrow Q(x))) \rightarrow R(a) \right) \rightarrow p(a) \land \neg \neg p(a)
\]

and \(SM[F; p]\) is satisfiable.

10.8 Proofs

**Proof of Theorem 31**

Since \(FO(T)\) contains no occurrences of predicates from \(P_P\), from the splitting theorem (Theorem 12), it follows that

\[
SM[FO(T) \land FO(P); P_P]
\]

is equivalent to

\[
FO(T) \land SM[FO(P); P_P].
\]

Hence the result. \(\Box\)

**Proof of Theorem 32**

If \(P\) is weakly safe and datalog safe, then \(P'\) is the same as \(P\). Assume that \(P\) is weakly safe but not datalog safe. Then, there is a rule that contains some variable \(y\) that occurs only in a negative datalog literal. \(P'\) is obtained from \(P\) by removing all negative datalog literals that contain such a variable \(y\). By Theorem 12, since \(FO(T)\) contains no predicate from \(P_P\),

\[
SM[FO(T) \land FO(P); P_P]
\]
is equivalent to
\[ FO(T) \land SM[FO(P); P_P]. \]

Similarly
\[ SM[FO(T) \land FO(P'); P_P] \]
is equivalent to
\[ FO(T) \land SM[FO(P'); P_P]. \]

So, it is sufficient to show that \( SM[FO(P); P_P] \) is equivalent to \( SM[FO(P'); P_P] \).

Since \( P \) is semi-safe relative to \( P_P \), \( P' \) is also semi-safe relative to \( P_P \). By Proposition 5 and Theorem 9 from (Ferraris et al., 2011), it is sufficient to show that under the assumption \( SPP^P_{c(P)} \), where \( c(P) \) is the set of object constants occurring in \( P \),
\[
(q \leq P_P) \rightarrow (FO(P)^*(q) \leftrightarrow FO(P')^*(q))
\] (10.8)
is logically valid. Given a rule, let \( F(y) \) be the conjunction of negative datalog literals that contain a variable occurring only in a negative datalog literal, where \( y \) is the list of all such variables. Formula (10.8) is logically valid, since \( (\exists y F(y))^*(q) \) is equivalent to \( \exists y F(y) \) under the assumption \( q \leq P_P \), and \( \exists y F(y) \) is equivalent to \( \top \) under the assumption \( SPP^P_{c(P)} \) (the extents of predicates in \( P_P \) are finite) and the standard name assumption (there are infinitely many objects in the domain). \( \square \)

**Proof of Theorem 34**

In the following, \( X \) and \( Y \) are Herbrand interpretations of \( \langle C, P_P \rangle \) such that \( Y \) is a subset of \( X \) (we identify an Herbrand interpretation with the set of ground atoms that are true in it), \( q \) is a list of new predicate constants of the same length as \( P_P \), and \( Y_q^{P_P} \) is obtained from \( Y \) by replacing every predicate constant in \( P_P \) with the corresponding predicate constant in \( q \).
**Proof of Theorem 34**  It is clear that $X \models_T P$ iff $X \models_T sP^{X}_T$. If $X \not\models_T P$, then $X$ is not a strong answer set of $\langle T, P \rangle$, and $X$ does not satisfy $SM^*[FO(P); P_T]$ relative to $T$.

Assume $X \models_T P$. It is sufficient to prove that, for any rule (10.6) in $P$, and any Herbrand interpretation $Y$ that is a subset of $X$,

$$Y \models_T s(a \leftarrow B, N)^X_T$$

if

$$X \cup Y^{P_p}_q \models_T (B \land N)^{s*}(q) \rightarrow a^{s*}(q).$$

**Case 1:** $s(a \leftarrow B, N)^X_T$ is empty. Clearly, $Y \models_T s(a \leftarrow B, N)^X_T$. It also follows that $X \models_T b$ for some *not* $b$ in $N$, or $X \not\models_T b$ for some $b \in DL^2_P \cap B$.

**Subcase 1:** Assume that $X \models_T b$ for some *not* $b$ in $N$. It follows from the definition of $F^{s*}$ that $X \cup Y^{P_p}_q \not\models_T (\neg b)^{s*}(q)$. Consequently, it follows that $X \cup Y^{P_p}_q \models_T (B \land N)^{s*}(q) \rightarrow a^{s*}(q)$.

**Subcase 2:** Assume that $X \not\models_T b$ for some $b \in DL^2_P \cap B$. It follows from the definition of $F^{s*}$ that $X \cup Y^{P_p}_q \not\models_T (b)^{s*}(q)$. Consequently, it follows that $X \cup Y^{P_p}_q \models_T (B \land N)^{s*}(q) \rightarrow a^{s*}(q)$.

**Case 2:** $s(a \leftarrow B, N)^X_T$ is not empty. Assume that $s(a \leftarrow B, N)^X_T$ is a $a \leftarrow B_1$. This implies that $X \not\models_T b$ for every *not* $b$ in $N$, and $X \models_T b$ for every $b \in DL^2_P \cap B$. If $b$ is monotonic, then $b^{s*}(q) \rightarrow b$ is logically valid, otherwise, $b^{s*}(q) = b$. This implies that $X \cup Y^{P_p}_q \models_T N^{s*}(q)$, and $X \cup Y^{P_p}_q \models_T b^{s*}(q)$ for all $b \in DL^2_P \cap B$. Since $a$ is an atom and $B_1$ is a set of atoms and monotonic dl-atoms, it is clear that $Y \models_T a \leftarrow B_1$ iff $X \cup Y^{P_p}_q \models_T B^{s*}(q) \rightarrow a^{s*}(q).$ \qed
**Proof of Theorem 33**

Similar to the proof of Theorem 34 shown above, using the fact that for every dl-atom $b$, $b^w_q(q) = b$.

**Proof of Theorem 35**

The following lemma extends Lemma 8 to dl-formulas.

**Lemma 16** For any dl-formula $F$, $X \cup Y_q^{P_p} \models_T (\neg F)^*(q)$ iff $X \models_T \neg F$.

**Proof.** By induction on $F$. $\square$

**Proof of Theorem 35** Without loss of generality, let us assume that $P$ is a variable-free program obtained by grounding. It is clear that $X \models_T P$ iff $X \models_T sP^X_T$. If $X \not\models_T P$, then $X$ is not a strong answer set of $(T, P)$, and $X$ does not satisfy $SM^w[FO(P); P_P]$ relative to $T$.

Assume $X \models_T P$. It is sufficient to prove that, for any rule (10.6) in $P$, and any Herbrand interpretation $Y$ that is a subset of $X$,

$$Y \models_T s(a \leftarrow B, N)^X_T$$

iff

$$X \cup Y_q^{P_p} \models_T (B \land N)^*(q) \rightarrow a^*(q).$$

**Case 1:** $s(a \leftarrow B, N)^X_T$ is empty. Clearly, $Y \models_T s(a \leftarrow B, N)^X_T$. Since no dl-atom in $B$ mentions $\ominus$, $B$ contains no dl-atoms from $DL^2_p$, and it follows that $X \models_T b$ for some $not b$ in $N$. Consequently, by Lemma 16, it follows that $X \cup Y_q^{P_p} \not\models_T (\neg b)^*(q)$, so that $X \cup Y_q^{P_p} \models_T (B \land N)^*(q) \rightarrow a^*(q)$.

**Case 2:** $s(a \leftarrow B, N)^X_T$ is not empty. Since no dl-atom in $B$ mentions $\ominus$, $B$ contains no dl-atoms from $DL^2_p$, and it follows that $s(a \leftarrow B, N)^X_T$ is $a \leftarrow B$. Also it
follows that $X \not\models b$ for every *not* $b$ in $N$, so that by Lemma 16, we get

\[ X \cup Y^{	ext{Pr}} \models_{\tau} N^*(q). \]

Since $a$ is an atom and $B$ is a set of atoms and monotonic dl-atoms, it is clear that $Y \models_{\tau} a \iff X \cup Y^{	ext{Pr}} \models_{\tau} B^*(q) \to a^*(q)$. \hfill \Box

**Proof of Theorem 36**

Similar to the proof of Theorem 35, using the fact that, by Lemma 16, for any dl-atom $A$, $X \cup Y^{	ext{Pr}} \models_{\tau} (\neg \neg A)^*(q)$ iff $X \models_{\tau} \neg \neg A$. \hfill \Box
Chapter 11

INTEGRATING ACTION THEORIES AND ONTOLOGIES

In this chapter, we present an approach to integrate circumscription action theories with ontologies, and show how this approach can be related to our approach for integrating rules and ontologies. We present an application of integrating action theories and ontologies in the context of a medical expert system that is required to assist physicians in diagnosis, treatment, and drug prescription. We also demonstrate our approach by using DLVHEX\(^1\), which is a well-known tool for reasoning with HEX-programs (Eiter, Ianni, Schindlauer, & Tmpits, 2005).

11.1 Integrating Circumscription Action Theories and Ontologies

As before, we consider ontologies that are based on Description Logics (DLs). Since circumscription extends first-order logic, integrating circumscription action theories and ontologies is rather straightforward. Below, we present our approach.

First, since the underlying signatures of the circumscription theories considered in this article are many-sorted, we define the union of two many-sorted signatures as follows. We denote a many-sorted signature by a pair \((S, C)\) where \(S\) is a set of sorts including the boolean sort \(\{true, false\}\), and \(C\) is a set of constants such that each constant in \(C\) of arity \(n\) is associated with argument sorts \(s_1, \ldots, s_n \in S\) and a value sort \(s \in S\). Given two many-sorted signatures \(\Sigma_1 = (S_1, C_1)\) and \(\Sigma_2 = (S_2, C_2)\) where each constant in \(C_1 \cap C_2\) is associated with the same arguments sorts and the same value sort in both the signatures, by \(\Sigma_1 \cup \Sigma_2\), we denote the signature \(\Sigma_{12} = (S_1 \cup S_2, C_1 \cup C_2)\) such that for every constant \(c \in C_1 \cup C_2\), if \(c \in C_i\), then \(c\) is associated with the same argument and value sorts in \(\Sigma_{12}\) and \(\Sigma_i\).

\(^1\)http://www.kr.tuwien.ac.at/research/systems/dlvhex/
Given a circumscriptive action theory $CA$ of a signature $\Sigma_{CA}$, and a DL knowledge base $T$ of a signature $\Sigma_T$ that does not contain any predicate constant from $\Sigma_{CA}$ that takes a timepoint/situation argument, the hybrid action theory $(T, CA)$ can simply be identified with the theory

$$CA \land FO(T)$$

of signature $\Sigma_{CA} \cup \Sigma_T$ where $FO(T)$ is the first-order representation of $T$. Below, we make this precise for each of the circumscriptive action theories considered in this article.

**Definition 4** Consider an event calculus theory (Chapter 7.1) $EC$ (of a signature $\Sigma_{EC}$) of the form

$$CIRC[\Sigma ; \text{Initiates, Terminates, Releases}] \land CIRC[\Delta ; \text{Happens}]$$

$$\land CIRC[\Theta ; Ab_1, \ldots, Ab_n] \land \Xi,$$

and a DL knowledge base $T$ of a signature $\Sigma_T$ that does not contain predicate constants from $\Sigma_{EC}$ that take arguments of sort timepoint (for example, HoldsAt, Initiates, Terminates, Releases, Happens, etc).

The hybrid action theory $(T, EC)$ is the theory

$$CIRC[\Sigma ; \text{Initiates, Terminates, Releases}] \land CIRC[\Delta ; \text{Happens}]$$

$$\land CIRC[\Theta ; Ab_1, \ldots, Ab_n] \land \Xi \land FO(T)$$

of signature $\Sigma_{EC} \cup \Sigma_T$.

**Definition 5** Consider a Lin’s causal situation calculus theory (Chapter 8.1) $SC$ (of a signature $\Sigma_{SC}$) of the form

$$CIRC[\mathcal{D}_{\text{caused}} ; \text{Caused}] \land \mathcal{D}_{\text{poss}} \land \mathcal{D}_{\text{rest}},$$
and a DL knowledge base $T$ of a signature $\Sigma_T$ that does not contain predicate constants from \{Holds, Caused, Poss\}.

The hybrid action theory $(T, SC)$ is the theory

$$CIRC[D_{\text{caused}}; \text{Caused}] \land D_{\text{poss}} \land D_{\text{rest}} \land FO(T) \quad (11.4)$$

of signature $\Sigma_{SC} \cup \Sigma_T$.

**Definition 6** Consider a Temporal Action Logics (TAL) theory (Chapter 9.1) $T, TAL$ (of a signature $\Sigma_{TAL}$) of the form

$$CIRC[\Gamma_{occ}; \text{Occurs}] \land CIRC[\Gamma_{depc} \land \Gamma_{acs}; \text{Occlude}] \land
\Gamma_{fnd} \land \Gamma_{time} \land \Gamma_{per} \land \Gamma_{obs} \land \Gamma_{domc}, \quad (11.5)$$

and a DL knowledge base $T$ of a signature $\Sigma_T$ that does not contain predicate constants from \{Holds, Occurs, Occlude\}.

The hybrid action theory $(T, T, TAL)$ is the theory

$$CIRC[\Gamma_{occ}; \text{Occurs}] \land CIRC[\Gamma_{depc} \land \Gamma_{acs}; \text{Occlude}] \land
\Gamma_{fnd} \land \Gamma_{time} \land \Gamma_{per} \land \Gamma_{obs} \land \Gamma_{domc} \land FO(T) \quad (11.6)$$

of signature $\Sigma_{TAL} \cup \Sigma_T$.

### 11.2 Relating Hybrid Action Theories to Hybrid Knowledge Bases

We now show how the above integration approach can be related to our approach for integrating DLs and ASP-rules presented in Chapter 10.1.

Since we have already related the circumscription action theories to ASP (Chapters 7.3, 8.1, and 9.3), we can use those results to relate hybrid action theories to hybrid knowledge bases. The following theorems give the precise relationship.
Theorem 37 Let \((T, EC)\) be a hybrid action theory (11.2) of signature \(\Sigma_{EC} \cup \Sigma_T\), and let \(F\) be the FOL-representation of the program obtained from \(EC\) by applying translation \(EC2ASP\) (Chapter 7.3). Then the following theories are equivalent \((\Sigma_{EC} \cup \Sigma_T)\)-equivalent to (11.2) :\(^2\)

(a) \(SM[\Sigma \cup I, T, R] \land SM[\Delta \cup H] \land SM[\Theta \cup Ab_1, \ldots, Ab_n] \land \Xi \land FO(T)\);

(b) \(SM[\Sigma \land \Delta \land \Theta \land \Xi \land FO(T) \land I, T, R, H, Ab_1, \ldots, Ab_n]\);

(c) \(SM[F \land FO(T) \land pr(F)]\).

Notice that the formula \((c)\) above is essentially how the hybrid knowledge base \((T, P)\), where \(P\) is the ASP-representation of \(F\), is identified according to our approach for integrating rules and ontologies (Chapter 10.1). The theorems below show similar results with respect to the situation calculus and TAL.

Theorem 38 Let \((T, SC)\) be a hybrid action theory (11.4) of signature \(\Sigma_{SC} \cup \Sigma_T\), and let \(F\) be the FOL-representation of the program obtained by applying translation \(F2LP\) on

\[D_{caused} \land D_{poss} \land D_{rest} \land D_{sit}\]  

(11.7)

(Chapter 8.1) with intensional predicates \{Caused, Poss, Sit\}. Then the following theories are \((\Sigma_{SC} \cup \Sigma_T)\)-equivalent to (11.4) :\(^2\)

(a) \(SM[D_{caused} \land D_{poss} \land D_{rest} \land FO(T)]\);

(b) \(SM[D_{caused} \land D_{poss} \land D_{rest} \land D_{sit} \land FO(T) \land Caused, Poss, Sit]\);

(c) \(SM[F \land FO(T) \land pr(F)]\).

\(^2\)For simplicity, the names of the circumscribed predicates are abbreviated. As before, we assume that \(\Xi\) is equivalently rewritten so that it does not contain strictly positive occurrences of the intensional predicates.
In the following theorem, we use $\Gamma_{ncirc}$ to denote the conjunction

$$\Gamma_{fnd} \land \Gamma_{time} \land \Gamma_{per} \land \Gamma_{obs} \land \Gamma_{domc}.$$  

**Theorem 39** Let $(T, TAL)$ be a hybrid action theory (11.6) of signature $\Sigma_{TAL} \cup \Sigma_T$, and let $F$ be the FOL-representation of the program obtained by applying translation $F2LP$ on

$$\Gamma_{occ} \land \Gamma_{depc} \land \Gamma_{acs} \land \Gamma_{ncirc}$$

with intensional predicates $\{\text{Occurs}, \text{Occlude}\}$. Then the following theories are $(\Sigma_{TAL} \cup \Sigma_T)$-equivalent to (11.6) :

(a) $SM[\Gamma_{occ}; \text{Occurs}] \land SM[\Gamma_{depc} \land \Gamma_{acs}; \text{Occlude}] \land \Gamma_{ncirc} \land FO(T)$ ;

(b) $SM[\Gamma_{occ} \land \Gamma_{depc} \land \Gamma_{acs} \land \Gamma_{ncirc} \land FO(T) ; \text{Occurs, Occlude}]$;

(c) $SM[F \land FO(T) ; pr(F)]$.

### 11.3 A Simple Application in the Healthcare/Biomedical Domain

Consider a medical expert system that is required to assist physicians in diagnosis and treatment of diseases/disorders. One of the important tasks of such a system would be to determine if a particular drug can be administered to the patient given his/her condition. To accomplish this task, an important question that the system needs to consider is "given the current condition of the patient, will prescribing a particular drug be beneficial to the patient or will it have adverse effects?". A lot of knowledge about the positive effects and contraindications of various drugs is available in the form of ontologies such as the National Drug File Ontology\(^3\). One possible way to answer the above question is to simply query the ontologies to check if a drug may treat the patient and if the patient is exhibiting any symptoms that are contraindications for prescribing the drug. However, such static inference

\(^3\)http://bioportal.bioontology.org/ontologies/40402
might be insufficient in certain cases and one might need to also consider if the current patient condition might lead to another condition which is a contraindication for prescribing the drug.

For example, consider the case where a patient is suffering from *Gastritis* and complains of abdominal *pain*. The job of the system is to determine if *Aspirin* can be recommended in this context. Assume that the biomedical ontology being queried has the information that "Aspirin may treat pain" and "Gastrointestinal Bleeding is a contraindication for administering Aspirin". Further, assume that we have the knowledge that Gastritis usually causes Gastrointestinal Bleeding. Now, if the system simply considers the current patient symptoms, it will simply conclude that Aspirin can be prescribed. However, since Gastritis usually causes Gastrointestinal Bleeding, this might not be the preferred treatment. On the other hand, if the system considers the knowledge about the effects of Gastritis, then it will be able to conclude that Aspirin is not recommended.

From the above example, it is clear that the system needs to consider what conditions the current patient condition might *cause* and then check whether any of the conditions is a contraindication to prescribing the drug. So, in addition to being able to query ontologies, the system also needs to be able to reason about various *cause-effect* relationships.

Following is a partial event calculus description for reasoning about the above context. In the description, there are three fluent names and 2 action names. Fluent *Administered*(\(d\)) is used to represent whether a drug \(d\) has been administered to the patient, fluent *Condition*(\(c\)) is used to represent if the patient is currently suffering from disease/disorder \(c\), and fluent *SideEffect*(\(d\)) is used to represent if the drug \(d\) has a side-effect on the patient. Action *Admin*(\(d\)) is used to represent the action of administering drug \(d\), and *DummyEvent*(\(c\)) is used to simulate the effects of condition \(c\). The predicates in all capitals (MAY_TREAT and
CONTRAINDICATION) are DL-predicates. MAY_TREAT(d, c) represents that drug d may treat c, and CONTRAINDICATION(d, c) represents that c is a contraindication for administering drug d.

\[
\text{Initiates}(\text{Admin}(d), \text{Administered}(d), t)
\]

\[
\text{HoldsAt}(\text{Condition}(c), t) \land \text{MAY_TREAT}(d, c) \land \neg \text{Ab}(d, t) \rightarrow 
\text{Terminates}(\text{Admin}(d), \text{Condition}(c), t)
\]

\[
\text{Ab}(d, t) \rightarrow \text{Initiates}(\text{Admin}(d), \text{SideEffect}(d), t)
\]

\[
\text{HoldsAt}(\text{Condition}(c), t) \land \text{CONTRAINDICATION}(d, c) \rightarrow \text{Ab}(d, t)
\]

These formulas represent the direct effects of administering a drug. The first formula represents that Admin(d) causes Administered(d) to be true after t. The second formula represents the positive effect of drug d w.r.t to treating the patient who is suffering from condition c. The third formula represents that administering a drug has a side-effect on the patient if the drug is contraindicated by a condition c from which the patient is suffering.

\[
\neg \text{Ab}_1(\text{Condition}(\text{Gastritis}), t) \rightarrow
\text{Initiates}(\text{DummyEvent}(\text{Gastritis}), \text{Condition}(\text{GastrointestinalBleeding}), t)
\]

\[
\text{HoldsAt}(\text{Condition}(c), t) \rightarrow \text{Happens}(\text{DummyEvent}(c), t)
\]

\[
\text{Initiates}(e, \text{Condition}(c), t) \land \text{HoldsAt}(\text{Administered}(d), t) \land
\text{CONTRAINDICATION}(d, c) \rightarrow \text{Initiates}(e, \text{SideEffect}(d), t)
\]

The first two formulas above represent that “Gastritis usually causes Gastrointestinal Bleeding”. The last formula represents the indirect effects of an event e that causes condition c. Essentially it says that if an event e causes condition c, and if a drug which is contraindicated by c has been administered, then the indirect effect of e is a side-effect.

\[
\neg \text{ReleasedAt}(f, 0)
\]

\[
\text{HoldsAt}(\text{Condition}(\text{Gastritis}), 0) \land \neg \text{HoldsAt}(\text{Administered}(d), 0) \land
\text{HoldsAt}(\text{Condition}(\text{Pain}), 0) \land \neg \text{HoldsAt}(\text{SideEffect}(d), 0) \land
\neg \text{HoldsAt}(\text{Condition}(\text{GastrointestinalBleeding}, \text{Tom}), 0)
\]
The first formula above represents that all the fluents are initially inertial, and the second formula represents the initial state. In addition to the above formulas, there are other axioms such as the unique name axioms for the fluents and actions, and the domain-independent axioms of the discrete event calculus (Chapter 7.1). Now, assuming that the ontology being queried entails the facts

- \text{MAY\_TREAT}(\text{Aspirin}, \text{Pain}),
- \text{MAY\_TREAT}(\text{Acetaminophen}, \text{Pain}), and
- \text{CONTRAINDICATION}(\text{Aspirin}, \text{GastrointestinalBleeding}),

one can verify the following from the above description:

- \text{HoldsAt}(\text{Condition}(\text{GastrointestinalBleeding}), \tau) holds for all \( \tau > 0 \);
- if \text{Happens}(\text{Admin}(\text{Aspirin}), \tau) holds for some timepoint \( \tau > 0 \), then \text{HoldsAt}(\text{SideEffect}(\text{Aspirin}), \tau_1) holds for all \( \tau_1 > \tau \);
- if \text{Happens}(\text{Admin}(\text{Aspirin}), \tau) holds for timepoint \( \tau = 0 \), then \text{HoldsAt}(\text{SideEffect}(\text{Aspirin}), \tau_1) holds for all \( \tau_1 \geq 2 \);
- if \text{Happens}(\text{Admin}(\text{Acetaminophen}), \tau) holds for some timepoint \( \tau \geq 0 \), then \( \neg \text{HoldsAt}(\text{Condition}(\text{Pain}), \tau_1) \) holds for all \( \tau_1 > \tau \), and \( \neg \text{HoldsAt}(\text{SideEffect}(\text{Acetaminophen}), \tau_1) \) holds for all \( \tau_1 \geq 0 \).

From this, the system will be able to conclude that Aspirin is not recommended but Acetaminophen can be recommended.

Due to the indirect effect axiom in the above description, if Aspirin is administered at some timepoint \( \tau \), and some contraindication to Aspirin is caused at some other timepoint \( \tau_1 > \tau \), then the system concludes that a side-effect is caused irrespective of the difference in the values of \( \tau \) and \( \tau_1 \). However, such a
conclusion might not be appropriate since the effects of Aspirin might have weared off before the contraindication is caused. One way to get over this problem is to treat action $\text{Admin}(d)$ as a durative action so that a side-effect can be caused only during the duration of the action. By setting the duration of the action to the time it takes for the effects of the drug to wear off, we can avoid any inappropriate conclusions about the side-effects.

Since TAL provides an ideal framework for representing durative actions, we will use it to encode the domain. Following is a partial TAL description in the surface language. Here, fluent $\text{Ab}$ is durational with default value $false$. The rest of the fluents are persistent.

\begin{align*}
\text{acs1} &\quad [t_1, t_2] \text{Admin}(d) \rightarrow ([t_1] \text{Condition}(c) \land \text{MAY_TREAT}(d, c) \land \\
&\quad \neg \exists c_1, t(t_1 \leq t \leq t_2 \land [t] \text{Condition}(c_1) \land \text{CONTRAINDICATION}(d, c_1)) \rightarrow \\
&\quad I((t_1, t_2) \neg \text{Condition}(c))) \\
\text{acs2} &\quad [t_1, t_2] \text{Admin}(d) \rightarrow \forall t(t_1 \leq t \leq t_2 \land [t] \exists c(\text{Condition}(c) \land \\
&\quad \text{CONTRAINDICATION}(d, c)) \rightarrow I([t, t_2] \text{SideEffect}(d))) \\
\text{dep1} &\quad \forall t([t] \text{Condition}(\text{Gastritis}) \land \neg \text{Ab}(\text{Gastritis}) \rightarrow \\
&\quad R([t + 1] \text{Condition}(\text{GastrointestinalBleeding})))
\end{align*}

The first statement above represents that if no contraindication to the drug $d$ holds in the interval $[t_1, t_2]$, then administering $d$, which may treat $c$, has a positive effect on the patient who is suffering from $c$. The second statement represents that if a contraindication to drug $d$ holds in the interval $[t_1, t_2]$, then administering $d$ in that interval causes a side-effect. Finally, the dependency constraint represents that $\text{Gastritis}$ usually causes Gastrointestinal Bleeding. Note here that due to the dependency constraint, we do not need the action $\text{DummyEvent}(c)$ which was used in the event calculus description. Another difference between the two descriptions is the introduction of the additional fluent $\text{Ab}$ to represent abnormality. This is because, while abnormality predicates are part of the language of the event
calculus, they are not part of the language of TAL. In addition to the above statements, there are other statements such as the unique value axioms, foundational axioms, etc. (Chapter 9.1).

Given the same initial state as before and the facts corresponding to MAY_TREAT and CONTRAINDICATION, one can verify the following from the above description:

- \( \text{Condition}(\text{GastrointestinalBleeding}) \) is true for all timepoints \( \tau \geq 1 \);

- if \( \text{Admin}(\text{Aspirin}) \) occurs in the interval \([0, 2]\), then \( \text{SideEffect}(\text{Aspirin}) \) is true for all timepoints \( \tau \geq 1 \);

- if \( \text{Admin}(\text{Acetaminophen}) \) occurs in the interval \([\tau_1, \tau_2]\), then
  \( \text{SideEffect}(\text{Acetaminophen}) \) is false for all \( \tau \geq 0 \), and \( \text{Condition}(\text{Pain}) \) is false for all \( \tau > \tau_1 \);

Now, consider an initial state in which only \( \text{Condition}(\text{Pain}) \) is true and the rest of the fluents are false. Further, assume that \( \text{Condition}(\text{GastrointestinalBleeding}) \) is not caused in some interval \([\tau_1, \tau_2]\). If \( \text{Admin}(\text{Aspirin}) \) occurs in the interval \([\tau_1, \tau_2]\), then \( \text{Condition}(\text{Pain}) \) is false for all \( \tau > \tau_1 \) and no side-effect will be caused. So, the system will be able to conclude that Aspirin can be recommended, unless a contraindication to it may be caused in the interval that it is to be administered.

11.4 A Simple Demonstration Using DLVHEX

DLVHEX\(^4\) is a system for reasoning with HEX-programs (Eiter et al., 2005). HEX-programs generalize answer set programs by allowing higher-order and external atoms. For the case when there are no higher-order atoms and all the external atoms are dl-atoms (Chapter 10.5), the semantics of HEX-programs coincides with that of non-monotonic dl-programs (Eiter & Wang, 2008) which we

\(^{4}\)http://www.kr.tuwien.ac.at/research/systems/dlvhex/
Figure 11.1: Sample Ontology in OWL

discussed in Chapter 10.5. So, by replacing the atoms MAY_TREAT(d, c) and
CONTRAINDICATION(d, c) with the corresponding dl-atoms, we can run the example
discussed in the previous section in DLVHEX. The sample ontology we use is
shown in Figure 11.1, which uses OWL.
DLVHEX (v. 1.7.2) uses the description logic reasoner RacerPro\(^5\) for querying ontologies. For our purpose, we use RacerPro version 1.9 for which we obtained an educational license. It is clear from the above ontology that the corresponding DL/first-order theory entails the following atoms:

- \text{may\_treat(Aspirin,Pain)};
- \text{may\_treat(Acetaminophen,Pain)}; and
- \text{contraindication(Aspirin,GastroIntestinalBleeding)}.

In order to run the event calculus and TAL descriptions using DLVHEX, we use F2LP to turn the descriptions into answer set programs. However, since F2LP outputs programs in the language of GRINGO and LPARSE, we use the python program \text{f2lpdlv.py}\(^6\) to turn the output of F2LP into the language of DLV and invoke DLVHEX on the resulting program. Also, since DLVHEX (v. 1.7.2) does not allow function constants (of arity > 0) in the input program, we cannot use reified constants to represent fluents as we do in the event calculus and TAL descriptions. To work around this issue, we flatten the fluents by introducing a predicate \text{equals}. For instance, \text{equals(f1,condition,pain)} represents that the constant \text{f1} represents the fluent \text{condition(pain)}. Similarly, \text{equals(e3,admin,aspirin)} represents that the constant \text{e3} represents the action/event \text{administer(aspirin)}. We include all these \text{declarations} and other facts in a data file, which is shown in Figure 11.2.

In the encoding shown in the figure, DRUGS is used as an abbreviation for the Unique Resource Identifier (URI)

\text{http://www.owl-ontologies.com/drugs.owl}

\(^5\) (Racer Systems GmbH & Co. KG) http://www.racer-systems.com
\(^6\) http://reasoning.eas.asu.edu/f2lp
which represents the namespace for the ontology. The actual encoding uses the latter. Similarly, FILE-LOC is an abbreviation for the actual location of the file.

Atoms &dlC[...](x) and &dlR[...](D,C) are the dl-atoms in the language of DLVHEX that are used to query DL concepts and roles respectively. For instance, the last rule in Figure 11.2 simply retrieves all pairs (d,c) such that may_treat(d,c) is entailed by the ontology shown in Figure 11.1, and adds them to the extent of may_treat. Note that while may_treat inside the construct &dlR[...] is a description logic predicate, the same predicate outside the construct belongs to the signature of the event calculus/TAL description. The construct #spatom{...} directs F2LP to copy any thing within the construct directly into the output program without any processing. This is useful to encode constructs that are not recognized by F2LP but are supported by the answer set solvers. For example, F2LP turns the last rule in Figure 11.2 into the following rule:

may_treat(D,C) :- &dlR[file:FILE-LOC","may_treat"](D,C).

Figure 11.3 shows the F2LP encoding of the event calculus description discussed in the previous section. To check if Aspirin can be administered to the patient at timepoint 0, we add the following to the description in Figure 11.3.

% query for Aspirin
#spatom{equals(E,admin,"<DRUGS#Aspirin>")} -> happens(E,0).
-(!#spatom{equals(F,condition,"<DRUGS#Pain>")}) &
  #spatom{equals(F1,sideEffect,"<DRUGS#Aspirin>")}) &
  -?T2: (holdsAt(F,T2) & T2 > 0) &
  -?T1: (holdsAt(F1,T1) & T1 > 0).

The first formula represents that Aspirin is administered at timepoint 0. The second formula is the negation of the query we want to check. The query here is to check if administering Aspirin treats the patient such that no side-effect is
caused after administering it. We can run the resulting theory using f2lpdlv.py as shown below.

```python
Python 2.7.1+ (r271:86832, Apr 11 2011, 18:13:53)
[GCC 4.5.2] on linux2
Type "help", "copyright", "credits" or "license" for more information.
>>> import f2lpdlv
>>> f2lpdlv.run('f2lp usecase-data usecase-ec dec',
              'dlvhex --filter=holdsAt')
```

The first argument to the program is the complete command line to run F2LP on the description. The second argument is the (partial) command line for invoking DLVHEX. The option --filter=holdsAt is used to supress all the predicates except holdsAt in the output. This produces the following answer set (the existence of an answer set indicates that the query is not entailed):

```plaintext
{ holdsAt(f6,1), holdsAt(f6,2), holdsAt(f4,2), holdsAt(f3,1),
  holdsAt(f3,2), holdsAt(f2,0), holdsAt(f2,1), holdsAt(f2,2),
  holdsAt(f1,0) }
```

In this output, holdsAt(f4,2) indicates that a side-effect is caused at timepoint 2. If we change the timepoint at which Aspirin is administered to 1, then we get the following output.

```plaintext
{ holdsAt(f6,2), holdsAt(f4,2), holdsAt(f3,1), holdsAt(f3,2),
  holdsAt(f2,0), holdsAt(f2,1), holdsAt(f2,2), holdsAt(f1,0),
  holdsAt(f1,1), holdsAt(f1,2) }
```

This output shows that in addition to a side-effect being caused, the pain is also not relieved (represented by holdsAt(f1,1), holdsAt(f1,2)). This is because at the time of administering Aspirin, fluent f3 (representing Gastrointestinal Bleeding) was true, thus defeating the positive effect axiom.
Running similar queries by replacing Aspirin with Acetaminophen produces no answer set as expected. Using these results, an expert system will be able to conclude that Acetaminophen can be recommended but Aspirin cannot be recommended.

% Gastritis "normally" causes gastrointestinalBleeding
#spatom{equals(E, dummyEvent, "<DRUGS#Gastritis>")} &
#spatom{equals(F, condition, "<DRUGS#GastroIntestinalBleeding>")} &
-#spatom{ab1(condition, "<DRUGS#Gastritis>", T)}
-> initiates(E, F, T).

% Indirect effect is a sideEffect if contraindications
% surface after the drug is administered
equals(F, condition, C) & equals(F1, administered, D) &
equals(F2, sideEffect, D) & initiates(E, F, T) &
holdsAt(F1, T) & contraindication(D, C) -> initiates(E, F2, T).

% DummyEvent is triggered everytime a condition holds
equals(F, condition, C) & equals(E, dummyEvent, C) &
holdsAt(F, T) -> happens(E, T).

% initial state
#spatom{equals(F, condition, "<DRUGS#Gastritis>")} ->
holdsAt(F, 0).
#spatom{equals(F, condition, "<DRUGS#GastroIntestinalBleeding>")}
-> -holdsAt(F, 0).
#spatom{equals(F, condition, "<DRUGS#Pain>")} ->
holdsAt(F, 0).
equals(F, sideEffect, D) -> -holdsAt(F, 0).
equals(F, administered, D) -> -holdsAt(F, 0).
-releasedAt(F, T).

Figure 11.3: F2LP encoding of the event calculus description
Now, consider the F2LP encoding of the TAL description for the same example shown in Figure 11.4. In the encoding, for simplicity, we introduce the abnormality predicate instead of the abnormality fluent. Given the initial state in which only \textit{Condition(Pain)} and \textit{Condition(Gastritis)} hold, if we want to check if Aspirin can be administered in the interval $[0, 2]$, then we add the following to the theory in Figure 11.4.

\% initial state
\begin{verbatim}
# spatom{equals(F,condition,"<DRUGS#Gastritis>")} -> holds(0,F,true).
# spatom{equals(F,condition,"<DRUGS#GastroIntestinalBleeding>")}
   -> holds(0,F,false).
# spatom{equals(F,condition,"<DRUGS#Pain>")} -> holds(0,F,true).
equals(F,sideEffect,D) -> holds(0,F,false).
\end{verbatim}

\% query
\% can aspirin be given to the patient?
\begin{verbatim}
# spatom{equals(E,admin,"<DRUGS#Aspirin>")} -> occurs(0,2,E).
- (# spatom{equals(F,condition,"<DRUGS#Pain>")} &
   # spatom{equals(F1,sideEffect,"<DRUGS#Aspirin>")} &
   holds(2,F,false)) & -?[T]: (T >= 0 & T <= 2 & holds(T,F1,true))).
\end{verbatim}

The first formula represents that Aspirin is administered in the interval $[0, 2]$, and the second formula is the negation of the query we want to check. The query here is to check if administering Aspirin treats the patient such that no side-effect is caused in the interval $[0, 2]$. We can run the resulting theory using \texttt{f2lpdlv.py} as follows.

```python
>>> f2lpdlv.run('f2lp usecase-data usecase-tal',
               'dlvhex --filter=holds')
```

\footnote{We disregard fluents $f6$ and $f7$ for the TAL description.}
% File: ’usecase-tal’

bool(true). bool(false).
#domain bool(Bo).
#domain bool(Bo1).

% all the fluents are persistent
equals(F,sidEffect,D) & #spatom(#succ(T,T1)) & -occlude(T1,F) ->
! [Bo]: (holds(T1,F,Bo) <-> holds(T,F,Bo)).

equals(F,condition,C) & #spatom(#succ(T,T1)) & -occlude(T1,F) ->
! [Bo]: (holds(T1,F,Bo) <-> holds(T,F,Bo)).

% Unique Value Axioms
holds(T,F,Bo) & holds(T,F,Bo1) & Bo != Bo1 -> false.
-? [Bo]: holds(T,F,Bo) -> false.

% holds is non-intensional
holds(T,F,Bo) | -holds(T,F,Bo).

% positive effect of drug
equals(E,admin,D) & occurs(T1,T2,E) & equals(F,condition,C) ->
((holds(T1,F,true) & may_treat(D,C) &
-? [F1,C1,T]: (T >= T1 & T <= T2 & holds(T,F1,true) &
equals(F1,condition,C1) & contraindication(D,C1)))
-> ![T]: (T > T1 & T <= T2 -> occlude(T,F) & holds(T,F,false))).

% negative effect of drug (sideEffect)
equals(E,admin,D) & occurs(T1,T2,E) & equals(F,condition,C) &
equals(F1,sidEffect,D) ->
((T3 >= T1 & T3 <= T2 & holds(T3,F,true) & contraindication(D,C))
-> ![T]: (T >= T3 & T <= T2 -> occlude(T,F1) & holds(T,F1,true))).

% Gastritis "normally" causes gastrointestinalBleeding
% using dependency constraints for this instead of dummy events
#spatom(equals(F,condition,"<DRUGS#Gastritis>")) &
#spatom(equals(F1,condition,"<DRUGS#GastroIntestinalBleeding>")) &
holds(T,F,true) & -#spatom(abl(condition,"<DRUGS#Gastritis">,T)) &
#spatom(#succ(T,T1)) ->
occlude(T1,F1) & holds(T1,F1,true).

Figure 11.4: F2LP encoding of the TAL description
Following is one of the answer sets produced (the existence of an answer set indicates that the query is not entailed):

\{ holds(0,f5,false), holds(0,f4,false), holds(0,f3,false),
  holds(0,f2,true), holds(0,f1,true), holds(1,f5,false),
  holds(1,f4,true), holds(1,f3,true), holds(1,f2,true),
  holds(1,f1,true), holds(2,f5,false), holds(2,f4,true),
  holds(2,f3,true), holds(2,f2,true), holds(2,f1,true) \}

This output indicates that a side-effect is caused at timepoint 1 and that administering Aspirin in the interval \([0, 2]\) does not relieve pain. Now, consider the initial state in which only \textit{Condition(Pain)} holds. Further, assume that \textit{Condition(Gastritis)} holds at timepoint 2. Running the same query as before produces no answer set, which indicates that the query is entailed. This in turn indicates that Aspirin can be administered in the interval \([0, 2]\). This is because the contraindication to Aspirin, which is Gastrointestinal Bleeding, is caused outside the interval in which Aspirin is administered.

As before, running similar queries by replacing Aspirin with Acetaminophen produces no answer sets. From these results, an expert system will be able to conclude that Acetaminophen can be recommended. It will also be able to conclude that Aspirin can be recommended, unless Gastrointestinal Bleeding may be caused in the interval in which it is to be administered.

11.5 Related Work

There has been considerable work done on integrating action formalisms and description logics (see, for example, (Baader, Lutz, Milicic, Sattler, & Wolter, 2005; Giacomo, Lenzerini, Poggi, & Rosati, 2006; Liu, Lutz, Milicic, & Wolter, 2006; Drescher & Thielscher, 2007; Gu & Soutchanski, 2007)). The primary difference between these approaches and our approach is that while these approaches focus on DL-based reasoning about actions, our approach focuses on integrating existing
circumscripive action theories with non-temporal DL knowledge bases. The goal of the DL-based approaches for reasoning about actions is to provide a decidable yet expressive logical framework for reasoning about actions. On the other hand, our goal is to provide a framework for ASP-based reasoning for circumscripive action theories which is capable of using ontologies as knowledge bases.

11.6 Proofs

Proof of Theorem 37

Follows from the straightforward application of Theorems 21, 22, and 12 (splitting theorem).

Proof of Theorem 38

Follows from the straightforward application of Theorems 23, 24, and 12 (splitting theorem).

Proof of Theorem 39

Follows from the straightforward application of Theorems 28, 29, and 12 (splitting theorem).
Developing formalisms that offer a suitable tradeoff between expressivity and computational efficiency is one of the fundamental goals of KR&R. Different existing formalisms have different limitations either with respect to expressivity or with respect to computational efficiency. Circumscription and DLs, which belong to the classical logic tradition, have certain limitations that are well-addressed by ASP, which belongs to the logic programming tradition. The vice-versa also holds. So, in this dissertation, we relate/integrate the formalisms using the framework of the first-order stable model semantics to (partially) overcome some of their limitations.

By relating circumscription to ASP, we are able to use answer set solvers for computing the event calculus, the situation calculus, and TAL. As shown earlier, this has several advantages with respect to both expressive and efficient reasoning. By integrating DLs and ASP, we are able to perform nonmonotonic reasoning using DL knowledge bases, thus providing a framework for integrating rules and ontologies for the semantic web. Further, since we use the same framework for relating circumscription to ASP, and for integrating DLs and ASP, we are able to reformulate the problem of integrating action theories and ontologies as a problem of integrating rules and ontologies, thus enabling us to use the computational tools of the latter for the former. We showed an application of this in the area of medical expert systems.

This dissertation also highlights the usefulness of the first-order stable model semantics as a mathematical tool for relating/integrating different knowledge representation formalisms, and for extending some well-known properties of traditional ASP to more general programs. Since the first-order stable
model semantics extends both first-order logic and ASP, it provides an ideal
framework for relating/integrating formalisms belonging to the different traditions of
classical logic and logic programming. Since some useful constructs in ASP, such
as “choice” and the “count” aggregate expression, can be viewed as abbreviations
for certain first-order formulas, the safety and splitting properties can be extended
to programs with these constructs by extending them to the first-order stable
model semantics.

This dissertation contributes to the following areas of KR&R:

- **Reasoning about Actions**: We present effective, ASP based computational
  approaches for the event calculus, the situation calculus, and TAL.

- **Theory of Stable Models and Answer Set Programming**: We present
  some interesting properties of the first-order stable model semantics and
  relate the stable model semantics to circumscription and circumscriptive
  action theories. We also extend the traditional safety and splitting properties
to a more general and useful class of programs.

- **Integrating Different Knowledge Representation Formalisms**: We
  present simple and effective approaches to integrate DLs and ASP, and
circumscripive action theories and ontologies.
